CHAPTER 9

SUBCLINICAL HYPOTHYROIDISM AND COGNITIVE FUNCTION IN PEOPLE OVER 60 YEARS: A SYSTEMATIC REVIEW AND META- ANALYSIS.

Abimbola A. Akintola Steffy W. Jansen David van Bodegom Jeroen van der Grond Rudi G. Westendorp Anton J.M. de Craen Diana van Heemst

Front Aging Neurosci. 2015 Aug 11;7:150.

ABSTRACT

Subclinical hypothyroidism (SCH), defined as elevated thyroid stimulating hormone and normal thyroid hormone levels, and cognitive impairment are both common in older people. While the relation between overt hypothyroidism and cognitive impairment is well established, data on the association between SCH and cognitive impairment are conflicting. This systematic review and metaanalysis was performed to assess available evidence on the association of SCH with cognition in community dwelling, relatively healthy older adults.

PubMed, EMBASE, Web of Science, COCHRANE, CINAHL, PsycINFO and Academic Search Premier (January 1966 to April 1, 2015) were searched without language restrictions, as were references of key articles, for studies on the association between SCH and cognition in older adults (> 60 years). These studies were reviewed by two independent reviewers according to predefined criteria for eligibility and methodological quality, and data extracted using standardized forms.

Of the 844 reports initially identified, 270 remained after exclusion of duplicates. Of the 270, fifteen studies comprising 19,944 subjects, of whom 1,199 had subclinical hypothyroidism were included. Data from the 15 studies was pooled, and meta- analyzed cross-sectionally for global cognition (MMSE), executive function, and memory, using random effects models. Pooled effect size (ES) for MMSE was -0.01 (95% CI -0.09, 0.08), with heterogeneity (I²) of 55.1%. Pooled ES was <0.001 (95% CI -0.10, 0.09) for executive function (I² = 13.5%), and 0.01 (95% CI -0.12, 0.14) for memory (I² = 46.9%). In addition, prospective analysis including four studies showed pooled ES of 0.033 (95% CI -0.001-0.067) for MMSE (I² <0.001%), indicating that subclinical hypothyroidism was not significantly associated with accelerated cognitive decline.

This systematic review and meta-analysis provides no evidence that supports an association between SCH and cognitive impairment in relatively healthy older adults.

INTRODUCTION

Overt adult onset hypothyroidism, which is marked by elevated thyroid stimulating hormone (TSH) levels and reduced levels of circulating thyroid hormones, has been associated with increased risk of deficits in specific cognitive domains including attention, concentration, memory, perceptual function, language, executive function and psychomotor speed ⁽¹⁻⁴⁾. However, controversies persists as to whether subclinical hypothyroidism (SCH), defined as mild elevation of TSH in the presence of normal free thyroxine (fT4), is associated with these specific cognitive domains. This is especially relevant in the older adults, as the prevalence of subclinical hypothyroidism increases with age and is estimated to be up to 22% in women aged more than 60 years and somewhat lower in men ^(5, 6).

Many studies have investigated whether subclinical hypothyroidism is associated with increased risk of cognitive impairment ⁽⁷⁻²¹⁾. However, the data are conflicting, and epidemiological studies that investigated this relationship have reported inconsistent findings. Furthermore, due to use of different TSH cut- off values, methodological differences, application of varying cognitive tests for different cognitive domains, and diverse reporting of results by these studies, the interpretability and comparability of their findings are hindered.

Here, we performed a systematic review of available evidence from both crosssectional and prospective studies on the association between subclinical hypothyroidism and cognition in the older adults. Furthermore, we performed a meta- analysis to quantify the magnitude of the associations between subclinical hypothyroidism and both global cognition as well as two specific cognitive domains, namely executive function and memory.

METHODS

Data sources and search strategy

A systematic literature search was conducted of articles published from January 1966 to April 1, 2015 on the association between subclinical hypothyroidism and cognition in the elderly. PubMed, EMBASE, Web of Science, COCHRANE, CINAHL, PsycINFO and Academic Search Premier were searched (Datasheet 1). The design of the electronic search

9

strategy was done in consultation with an expert information specialist. A thorough search was conducted on the bibliographies of key articles in the field and these were included in this review. To avoid missing any relevant study in the search, broadly defined terms were used (Datasheet 1). Reference lists of key articles were also searched for relevant articles that could have been missed.

Study selection

Two independent reviewers (AAA and SWJ) screened the extracted citations for eligibility. To maximize the quality and comparability of the studies, general inclusion and exclusion criteria were defined a priori (Table 1). The titles, abstracts and later the full- texts of the search results were screened- the studies included were those that assessed the cognitive status of relatively healthy (community dwelling, and considered healthy by the authors of the original articles) elderly (aged 60 years and above) participants with subclinical hypothyroidism.

Subclinical hypothyroidism is defined as elevated TSH and normal fT4 ⁽²²⁾. However, controversies exist as to the upper limit of the TSH reference range. Several reviews suggest a TSH upper limit of 4.5 to 5.0 mU/L (22, 23), but some authors suggest that the upper limit of the TSH range should be reduced to 2.5 to 3.0 mU/L, based on a higher risk of progression to overt hypothyroidism and a higher prevalence of anti-thyroid antibodies than in euthyroid participants (24). In the absence of a consensus, the use of a specific TSH upper limit was not pre-specified in this systematic review to define subclinical hypothyroidism. Furthermore, fT4 values were considered normal if indicated as normal by the authors, even if data on fT4 were not presented.

Studies done on participants with depression (according to the Diagnostic and Statistical Manual of Mental Disorders (DSM) criteria), dementia, psychiatric symptoms, neurological disorders e.g. Parkinson's disease, and other chronic systemic illnesses were excluded. Furthermore, participants using thyroid medications were excluded. Three relatively large studies that measured health status of participants with an elevated TSH were initially included. However, they were later excluded because assessment of mood, general and mental health status was done qualitatively, without specifying whether global cognition or specific cognitive domains were measured ⁽²⁵⁻²⁷⁾.

Inclusion criteria	Exclusion criteria
Human studies	Animal studies
Median/mean age 60 or above	Younger than 60
Subclinical hypothyroidism (SCH)-	SCH not defined
• Elevated TSH and normal fT4;	
• All self-defined subclinical hypothyroidism	
Elevated serum TSH in association with normal total or free T4 and T3 values	
- High-normal TSH and abnormal response to TRH	
Elevated serum TSH with normal thyroid hormone - levels, without symptoms that could be explained by overt hypothyroidism	
Relatively healthy elderly participants: Healthy as determined by the authors of the original articles	Full blown depression, psychiatric symptoms, neurological disorders as Parkinson's disease or predefined dementia, substance abuse
Free living/ community dwelling	Hospitalized patients
Original research articles Including prospective studies, randomized-controlled trials, etc. that provide baseline data	Systematic reviews, meta- analyses, reviews, conference abstracts, web pages.
Cognitive measure and domain specified	Cognitive domain not well defined, e.g. 'mood', 'quality of life', 'mental health' etc.
All languages	
	Duplicates

TABLE 9.1 | Selection criteria for eligibility for inclusion or exclusion

Data extraction and quality assessment

From each study that met the eligibility criteria, information was extracted about study design (prospective or cross-sectional), participant characteristics, criteria used to define subclinical hypothyroidism, cognitive tests applied and domains tested, and study results (effect estimates, variables included for adjustments, or matching procedures) using a standardized data- collection form.

The two reviewers (AAA and SWJ) independently assessed the methodological quality of included studies using a pre- defined list of criteria ^(28, 29) (Datasheet 2). In total, 11 key indicators were used to systematically assess study quality. These were 1) clarity of hypothesis, 2) population studied (convenience sample versus population-based, defined as a random sample of the general population, 3) clear definition of subclinical

hypothyroidism (indication of TSH cut-off and fT4 values that were used in the study), 4) detailed description of study materials and methods, 5) validity of measurements and cognitive tests, 6) number of cognitive domains tested (global cognition, executive function and/ or memory), 7) clear description of statistical methods, 8) adjustments/ correction for potential confounders, 9) clear presentation of results, 10) generalizability to other populations, and 11) method of outcome adjudication (use of formal adjudication procedures, defined as having clear criteria for the outcome (cognitive impairment). A score of "0" (lacking), "1"(incomplete) or "2" (complete) was assigned to each of the key indicators per study, with a maximum total score of 22.

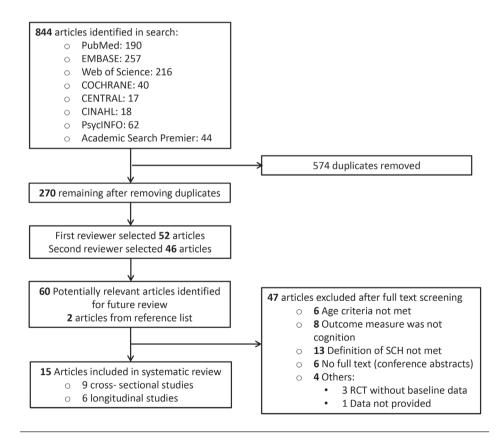

FIGURE 9.1 | Flowchart showing the literature search for the systematic review.

Data synthesis and statistical analysis

Authors were contacted when necessary to request more detailed data on the association between subclinical hypothyroidism and cognition in older adults ⁽¹⁰⁻¹²⁾. The most adjusted estimates and SD/SE were used for analysis, where available. In instances where participants were divided into groups based on TSH values (tertiles/ quartiles), the mean TSH value for the whole group was used.

Data was qualitatively synthesized and assessed for the number of participants that were included, the definition of subclinical hypothyroidism applied, the cognitive tests that were used and the cognitive domains that were measured. Meta-analysis was done by comparing estimates from participants with subclinical hypothyroidism with those from euthyroid participants, using data from both cross- sectional studies and baseline data from prospective studies for the cross- sectional analysis. Thus, only studies that provided these estimates were included in the meta- analysis. Using Hedges method ⁽³⁰⁾, pooled estimates with standard error were calculated first from cross- sectional analysis of available studies, and then for the prospective data, using the same approach.

To make effect estimates comparable between studies, effect sizes (ES) were calculated from calculated means with standard deviation of participants with subclinical hypothyroidism compared to euthyroid participants. For studies that used > 1 cognitive test ^(9, 12, 14, 16, 17, 20), a pooled ES was calculated for each study. After calculating an ES for each study, a meta- analysis was performed using a random effects model. The random effects model was applied, because it takes into account the heterogeneity between the studies. All statistical analyses were performed using STATA version 10. Cochrane Q test and I² index with a conservative p-value of 0.10 was used to evaluate the heterogeneity across individual studies. I² values of < 25% was considered reflective of low, between 25 and 50% of moderate and > 50% of high heterogeneity between studies.

RESULTS

Study selection

Of the 844 reports initially identified, 270 remained after exclusion of duplicates. Of the 270 reports, 210 were excluded that were unrelated to the association between subclinical hypothyroidism and cognition in the elderly (Figure 1), leaving 60 articles for full text

analysis. Two more articles were selected from reference lists of relevant articles. Of the 62 articles that were selected for detailed (full text) evaluation, full texts were not available for six studies. Additionally, ten studies were excluded because the participants were not considered healthy, another thirteen because the definition of subclinical hypothyroidism (high TSH and normal fT4) was not met and four because data was not available for systematic review (three were randomized controlled trials (RCTs) without baseline data, and one study that reported qualitative results). Furthermore, eight studies that did not measure cognition as endpoint were excluded- these either measured mental health by means of questionnaires, or studied depression. Six other studies were excluded because the mean/ median age of the participants was less than 60 years (Figure 1).

Two studies each were reported in Spanish and Dutch respectively, one in Italian and another in Czech. The researchers (AAA and SWJ) themselves translated the two Dutch articles into English. Another article was translated from Czech to English by the author himself⁽³¹⁾. The other foreign language articles were translated to English by the researchers' colleagues that spoke the language. These articles were all later excluded after full- text analysis. When similar data were published more than once ^(12, 32, 33), the article with the most definitive and extractable data was included ⁽¹²⁾. A study was later dropped because it studied the effect of subclinical hypothyroidism on demented and non-demented elderly using only clinical dementia rating, thus was incomparable with the other selected studies in terms of results ⁽³⁴⁾. Fifteen observational studies met the eligibility criteria.

Study characteristics

Table 2 shows the characteristics of the nine cross- sectional and six prospective studies that were included in the review. In total, the 15 studies comprised 19, 944 participants, of whom 1,199 had subclinical hypothyroidism. The upper reference limit of TSH (TSH cut-off) to define subclinical hypothyroidism ranged from 3.6 mU/L to 10 mU/L. A total of 13 out of the 15 studies also reported fT4 measurement. The studies used varying cognitive tests to measure a wide range of cognitive domains. The cognitive domains that were covered included global cognition, executive function, memory, general intelligence, attention and concentration, visio- spatial organization, language, and cognitive or psychomotor speed. These cognitive domains were merged into three main domains, namely global cognition, executive function and memory, as shown in Table 3. The cognitive tests that were used for each of these cognitive domains are also presented in Table 3.

Systematic review

In total, 1,199 participants with subclinical hypothyroidism were included in the systematic review. From the 15 studies in our systematic review, 12 studies indicated a lack of significant association between subclinical hypothyroidism and cognitive impairment in the elderly. These studies comprised 1,109 participants with subclinical hypothyroidism and therefore contributed 92.5% of the population sampled and to the outcome of the systematic review. Of the remaining three studies, two found an association, and one was inconclusive ⁽¹³⁾. The inconclusive study demonstrated an association between log transformed TSH levels with decreasing MMSE performance in hypothyroid participants, but it was not specified whether the observed association was with overt hypothyroidism or with subclinical hypothyroidism. This study was included in the systematic review but excluded from meta- analysis.

A total of two studies found an association between subclinical hypothyroidism and cognition in the elderly. The first study found (in 15 participants with subclinical hypothyroidism) that high TSH levels were associated with worse verbal memory and MMSE scores but not speed of performance ⁽⁹⁾. The second study found (in 42 participants with subclinical hypothyroidism) that performance in MMSE and Prose memory test were lower in participants with subclinical hypothyroidism compared to euthyroid participants ⁽¹⁸⁾. Performance in matrix test was also slightly lower in subclinical hypothyroidism, but this was not significant. Summarily, from the studies that observed a significant association between subclinical hypothyroidism and cognitive impairment, the cognitive domains affected were global cognition as assessed via MMSE; executive function as assessed via matrix test; and memory as assessed via auditory verbal learning test, prose memory test, and verbal fluency. The two studies combined comprised 57 participants with subclinical hypothyroidism and contributed only 4.75% to the overall population with subclinical hypothyroidism and to the outcome of the systematic review.

Meta- analysis

To assess whether subclinical hypothyroidism was associated with impairment of various cognitive domains, we analyzed MMSE separately as a measure of global cognition. Ten out of the 15 studies provided MMSE results either at baseline or at follow- up. The rest of the cognitive tests were categorized into tests of executive function or of memory, as shown in Table 3. Data from the 15 studies was pooled first for cross- sectional analysis, and

meta- analyzed separately for global cognition (MMSE), executive function, and memory. The pooled effect size (ES) for MMSE was -0.01 (95% CI -0.09, 0.08), with heterogeneity (I²) of 55.1% (Figure 2A). Pooled ES was < 0.001 (95% CI -0.10, 0.09) for executive function (I² = 13.5%) (Figure 2B), and 0.01 (95% CI -0.12, 0.14) for memory (I² = 46.9%) (Figure 2C). These analyses indicated that available evidence does not support an association of subclinical hypothyroidism with worse performance in MMSE, executive function or global cognition.

Prospective analysis was done for MMSE in four studies from which prospective data was available (Figure 3). The pooled ES was 0.03 (95% CI -0.001-0.07) P = 0.055, with heterogeneity (I²) of <0.001%. Thus, subclinical hypothyroidism was not significantly associated with accelerated decline of global cognition, as assessed by MMSE. Due to the small number of available studies, prospective analysis was not done for executive function or memory.

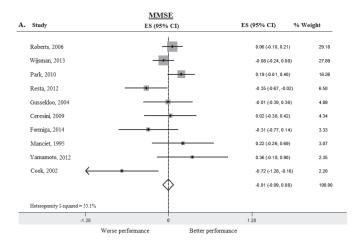

Subgroup and sensitivity analyses

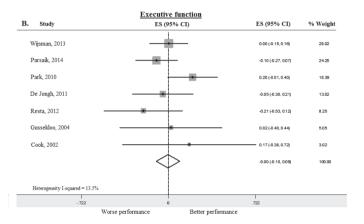

Subgroup analyses were performed on studies with similar TSH cut- off values, and in studies with similar study design (cross- sectional or prospective). The effect sizes of these different subgroups were essentially similar, indicating that in this meta- analysis, subclinical hypothyroidism was not significantly associated with cognitive impairment.

DISCUSSION

On the basis of the findings of this systematic review and meta- analysis we did not find evidence supporting an association of subclinical hypothyroidism with cognitive impairment in relatively healthy, community- dwelling elderly. Out of 15 observational studies, only two small cross-sectional studies ^(9, 18) observed statistically significant associations between subclinical hypothyroidism and cognitive impairment, namely global cognition (MMSE), and memory. All other studies indicated a lack of association. No evidence was found that the lack of association between subclinical hypothyroidism and cognitive impairment was limited to unadjusted studies, or to studies of lower methodological quality. Meta-analysis of studies from which data for cross sectional analysis could be retrieved, revealed lack of association between subclinical hypothyroidism and global cognition (assessed by MMSE) as well as lack of association of subclinical hypothyroidism with memory and executive function. Subgroup analyses by type of study design showed a similar trend in the prospective cohort studies group compared with the cross-sectional studies. We also did not find evidence supporting an association of subclinical hypothyroidism with

9

Subclinical hypothyroidism and cognition in older adults

cognitive impairment in a prospective analysis. However, the number of studies retrieved for prospective analysis was low and the study quality (assessed by scoring based on key indicators) varied.

Our results are in line with previous focused reviews ^(35, 36) supporting a lack of association between subclinical hypothyroidism and cognitive impairment that largely drew upon the results from large population based studies ⁽³⁷⁾. In contrast, another review conducted on the association between TSH and cognitive impairment in community dwelling and hospitalized elderly ⁽³⁸⁾ reported some evidence supporting the association between subclinical hypothyroidism and cognitive impairment, which was driven by studies showing an association between thyroid hormones and dementia. Thus, previous observational studies on the association of cognition impairment and subclinical hypothyroidism have yielded conflicting results. Our finding of lack association between subclinical hypothyroidism and cognitive impairment is also in line with the results of two placebo controlled randomized clinical trials ^(36, 39) that showed no effect of treatment with T4 on cognitive endpoints in participants with subclinical hypothyroidism.

To our knowledge, this is the first meta- analysis to examine the cross- sectional and prospective associations between subclinical hypothyroidism and cognitive impairment using available evidence. By pooling the data from the 15 studies, a total of 19, 944 participants, of whom 1, 199 had subclinical hypothyroidism were analyzed. This increased the power to detect potential associations and reduced the probability of false-negative results ⁽¹⁸⁾. Case-control and cross-sectional studies are more susceptible to bias, particularly selection bias for case-control studies ⁽⁴⁰⁾. Although bias cannot be excluded, almost all the cross-sectional studies that fulfilled our quality criteria demonstrated the absence of a statistically significant association between subclinical hypothyroidism and cognitive impairment ^(13, 16).

Overt hypothyroidism has been associated with global cognitive impairment as well as with impairments in various cognitive domains, notably in memory and executive function. Because thyroid dysfunction can be seen as a continuum, it has been hypothesized that subclinical hypothyroidism might also be associated with mild cognitive impairment. The inverse physiological relationship between circulatory levels of TSH and thyroid hormones implies that in subclinical hypothyroidism, thyroid hormone action may be slightly reduced (even though circulatory thyroid hormones are still in the normal range), which might be associated with subtle defects in specific cognitive domains, including memory and executive function. Moreover, one might speculate that potential associations between subclinical hypothyroidism and cognitive impairment are stronger when TSH is markedly increased (TSH > 10 mlU/L) as compared to mild or moderate increases. Similarly, it was found previously that associations between subclinical hypothyroidism and risk for coronary heart disease and mortality were strongest with a TSH concentration of 10 mlU/L or greater ⁽⁴¹⁾.

This analysis has four main limitations. Firstly, all data were obtained from observational studies, many of which are cross- sectional studies. There is a possibility of bias in the selection of included studies, bias and quality problems in the original studies, publication bias, heterogeneity, and confounding ⁽²⁹⁾. To limit bias in the selection of included studies, broad inclusion criteria were used for studies that provided quantitative data on the risk of cognitive impairment in elderly participants with subclinical hypothyroidism. Furthermore, sensitivity analyses were performed according to differences between the studies and methodological study quality, as recommended ^(29, 42). Many of the original studies did not have statistically significant results, thus a meta- analysis was conducted to increase the power to find an association. Still, the negative conclusion of this systematic review and meta- analysis may be limited by inherent biases and differences in study designs ⁽⁴³⁾. However, the sensitivity analyses performed did not suggest that the presented results meaningfully depended on differences in study designs or other study characteristics.

Secondly, the possibility of misclassification of subjects as having subclinical hypothyroidism cannot be ruled out ⁽⁴³⁾. In most of the studies, the diagnosis of subclinical hypothyroidism was based on single assessment of TSH, without repeated confirmatory TSH measurement. This could have resulted in inclusion of individuals with only transiently elevated TSH levels. Furthermore, none of the included studies used age-adjusted TSH reference ranges to enroll the subjects. Since increased age has been associated with an increase in the upper limit of the TSH reference range ⁽⁴⁴⁾, the use of unadjusted reference ranges may have resulted in misclassification of some elderly participants as having subclinical hypothyroidism. This misclassification may have resulted in underestimation of the association between subclinical hypothyroidism and cognition. However, since the 95% CI around the estimates are quite narrow and the misclassification is likely to be small, a large effect of subclinical hypothyroidism on cognition can be confidently ruled out.

Thirdly, the definitions of subclinical hypothyroidism and cognitive decline were slightly different between the studies. The use of different TSH cut-offs reflects the absence of consensus to define subclinical hypothyroidism ^(22, 23). Some studies used a TSH upper limit of less than 4.5 mU/L ^(9, 16), and the inclusion of those participants may have

blunted the effect of any observed associations, since they may not have had subclinical hypothyroidism ⁽²³⁾. However, the sensitivity analyses pooling more homogeneous studies gave similar results indicating a lack of evidence supporting an association of subclinical hypothyroidism with cognitive impairment. However, one might speculate that potential associations between subclinical hypothyroidism and cognitive impairment might only be present when TSH is markedly increased (TSH > 10m IU/L). Future studies using individual participant data should be directed at analyzing available evidence for an association between subclinical hypothyroidism and cognition on based TSH categories, as was done previously for associations between subclinical hypothyroidism and cognitical hypothyroidism and coronary heart disease ⁽⁴¹⁾.

Fourthly, there were several differences in methodologies and choice of cognitive domains that were tested in the studies in this systematic review and meta- analysis. Thus, we cannot exclude the possibility that subclinical hypothyroidism might be associated with subtle defects in specific domains that can only be identified using highly specific cognitive tests and measures. Indeed, functional neuro- imaging studies in participants with subclinical hypothyroidism and markedly elevated TSH levels has revealed impairments in working memory and brain areas associated with executive function that reversed by treatment with T4 ⁽⁴⁴⁾. However, the clinical relevance of such specific measures remains unclear. Moreover, different laboratory methods were used for the measurements of TSH and fT4. In addition, TSH has a distinct circadian rhythm and time of the measurements of TSH was not reported in the articles, which may have affected the results.

In conclusion, this systematic review and meta- analysis provides no evidence that supports an association between subclinical hypothyroidism and cognitive impairment in relatively healthy, community dwelling elderly. However, available prospective studies were limited. Thus, additional large, high- quality studies are needed that will allow for more extended analyses.
