Abstract

We present Hitomi observations of N132D, a young, X-ray bright, O-rich core-collapse supernova remnant in the Large Magellanic Cloud (LMC). Despite a very short observation of only 3.7 ks, the Soft X-ray Spectrometer (SXS) easily detects the line complexes of highly ionized S K and Fe K with 16–17 counts in each. The Fe feature is measured for the first time at high spectral resolution. Based on the plausible assumption that the Fe K emission is dominated by He-like ions, we find that the material responsible for this Fe emission is highly redshifted at $\sim 800 \text{ km s}^{-1}$ compared to the local LMC interstellar medium (ISM), with a 90% credible interval of 50–1500 km s^{-1} if a weakly informative prior is placed on possible line broadening. This indicates (1) that the Fe emission arises from the supernova ejecta, and (2) that these ejecta are highly asymmetric, since no blue-shifted component is found. The S K velocity is consistent with the local LMC ISM, and is likely from swept-up ISM material. These results are consistent with spatial mapping that shows the He-like Fe concentrated in the interior of the remnant and the S tracing the outer shell. The results also show that even with a very small number of counts, direct velocity measurements from Doppler-shifted lines detected in extended objects like supernova remnants are now possible. Thanks to the very low SXS background of ~ 1 event per spectral resolution element per 100 ks, such results are obtainable during short pointed or slew observations with similar instruments. This highlights the power of high-spectral-resolution imaging observations, and demonstrates the new window that has been opened with Hitomi and will be greatly widened with future missions such as the X-ray Astronomy Recovery Mission (XARM) and Athena.

Key words: ISM: supernova remnants — ISM: individual (N132D) — instrumentation: spectrographs — methods: observational — X-rays: individual (N132D)

1 Introduction

As the main drivers for matter and energy in the Universe, supernova remnants (SNRs) are excellent laboratories for studying nucleosynthesis yields and for probing the supernova (SN) engine and dynamics. Core-collapse SNRs, in particular, address fundamental questions related to the debated explosion mechanism and the aftermath of exploding a massive star.

The mechanism of core-collapse supernova explosions has been one of the central mysteries in stellar astrophysics. While one-dimensional simulations have failed to explode a star, only very recently, successful explosions of massive stars have been

achieved in three-dimensional simulations invoking convection or standing accretion shock instabilities (SASI; see Janka et al. 2016 for a recent review). The ejecta composition and dynamics as a function of the progenitor star’s mass and environment have formed another puzzle, with predictions largely relying on the assumption of spherically symmetric models and with yields that vary depending on metallicity, mass loss, explosion energy, and other assumptions (e.g., Nomoto et al. 2006; Woosley & Heger 2007).

Significant progress has been made to answer these central questions, thanks to high-resolution imaging and spectroscopic mapping of ejecta (in space and velocity) in core-collapse SNRs, including the oxygen-rich, very young and bright Cassiopeia A SNR in our Galaxy (Hwang & Laming

* The corresponding authors are Eric D. Miller, Hiroya Yamaguchi, Kumiko Nobukawa, Makoto Sawada, Masayoshi Nobukawa, Satoru Katsuda, and Hideyuki Mori.

2012; Grefenstette et al. 2014) and more evolved SNRs with ejecta signatures such as the O-rich Galactic SNRs G292.2+1.8 (Park et al. 2007; Kamitsukasa et al. 2014) and Puppis A (Hwang et al. 2008; Katsuda et al. 2013), and the ejecta-dominated SNR W49B (Lopez et al. 2013a, 2013b). While such observations have opened a new window to understanding the physics and aftermath of core-collapse explosions, several complications remain in interpreting the observations. First, resolving ejecta from the shocked interstellar medium (ISM) requires fine spectral resolution of extended objects in the X-ray. Second, there is a strong dependence of the elemental distribution and plasma state on both the evolutionary stage of the SNR and on the surrounding environment shaped by the exploded progenitor star. Mixed-morphology SNRs, expanding into an inhomogeneous medium and often interacting with molecular clouds, need the additional treatment of over-ionized (recombining) plasma, as opposed to under-ionized (ionizing) plasma in the younger remnants or SNRs expanding into a low-density and homogeneous medium (e.g., Ozawa et al. 2009; Uchida et al. 2015). The advent of high-spectral-resolution imaging detectors such as the Soft X-ray Spectrometer (SXS) aboard Hitomi has promised to revolutionize our three-dimensional mapping of ejecta dynamics and composition, while spectroscopically differentiating between shocked ejecta and the shocked circumstellar/interstellar environment shaped by the progenitor star (Takahashi et al. 2016; Hughes et al. 2014).

A natural early target for Hitomi was N132D, the X-ray brightest SNR in the LMC, with an age estimated to be ~ 2500 yr (Vogt & Dopita 2011). High-velocity ejecta were first detected and studied in optical wavelengths in N132D (Danziger & Dennefeld 1976; Sutherland & Dopita 1995; Morse et al. 1995; Morse et al. 1996). Optical/UV spectra from the Hubble Space Telescope show strong emission of C/Ne-burning elements (i.e., C, O, Ne, Mg), but little emission from O-burning elements (i.e., Si, S), leading to an interpretation of a Type Ib core-collapse supernova origin for this SNR (Blair et al. 2000).

In the X-ray band, the Einstein Observatory made the first observation of N132D, revealing its clear shell-like morphology (Mathewson et al. 1983) which has been interpreted as arising from the SN blast wave expanding within a cavity produced by the progenitor star's H II region (Hughes 1987). Einstein also performed the first high-resolution spectral observations with the Focal Plane Crystal Spectrometer (FPCS), clearly seeing strong oxygen and other emission lines and obtaining the first measurements of line flux ratios and constraints on the temperature and ionization state (Hwang et al. 1993). The following ASCA observations revealed that elemental abundances of the entire SNR are consistent with the mean LMC values. This suggests that the X-ray-emitting plasma is dominated by the swept-up ISM (Hughes et al. 1998). Beppo-SAX detected Fe K line

emission arising from a hot plasma (Favata et al. 1997). High-resolution X-ray images from XMM-Newton and Chandra have shown that the Fe K-emitting material is concentrated in the interior of the SNR, contrasting with the material emitting at softer energies of O, Ne, Mg, Si, S, and Fe L (Behar et al. 2001; Canizares et al. 2001; Borkowski et al. 2007; Xiao & Chen 2008; Plucinsky et al. 2016). X-ray emission from O-rich ejecta knots has also been discovered with Chandra, showing a spatial correlation with the optical O emission (Borkowski et al. 2007). The centroid and intensity of the Fe K line emission measured with Suzaku support the core-collapse origin (Yamaguchi et al. 2014). Very recently, a combined NuSTAR and Suzaku analysis revealed that the hot, Fe K-emitting plasma is in a recombining state with a large relaxation timescale of $\sim 10^{12} \text{ cm}^{-3} \text{ s}$, implying that the plasma underwent rapid cooling in the very beginning of its life (Bamba et al. 2017).

N132D is the brightest among all known SNRs in GeV and TeV bands (Ackermann et al. 2016; H.E.S.S. Collaboration et al. 2015). The spectral energy distribution from radio to gamma-rays including synchrotron X-rays detected with NuSTAR suggests that the gamma-ray emission originates from hadronic processes (Bamba et al. 2017). The total proton energy required to explain the spectral energy distribution was derived to be $\sim 10^{50} \text{ erg}$, showing that N132D is an efficient particle accelerator.

We here present Hitomi observations of N132D. These commissioning phase observations were expected to explore the emission line structure of the remnant with exquisite spectral resolution, unprecedented for an extended object at the energy of Fe K ($\sim 6.7 \text{ keV}$). Unfortunately, due to poor satellite attitude control during the majority of the observation (see section 2 for details), only a short exposure was obtained with the Hitomi/SXS microcalorimeter. Nevertheless, owing to the excellent spectral resolution and gain accuracy of the SXS, we detect spectral features of strong emission from S, Ar, and Fe, allowing us to investigate the bulk velocity of the shocked material in this SNR using the Doppler shift of these emission lines. We demonstrate the superior capability of high-resolution spectrometers particularly for low-statistics data, which provide positive prospects for future observations of distant or faint objects with future X-ray microcalorimeter missions, like the X-ray Astronomy Recovery Mission (XARM), Athena (Nandra et al. 2013), and Lynx¹. We also present the analysis of Soft X-ray Imager (SXI) data, simultaneously obtained from this observation but with longer exposure (and hence higher statistics) owing to its wide field of view (FoV).

This paper is organized as follows. In section 2, we describe the details of the Hitomi observations. We present spectral analysis of the SXS and SXI in sections 3 and 4, respectively. We discuss the results in section 5 and summarize in section 6.

¹ <https://wwwastro.msfc.nasa.gov/lynx>

Throughout the paper, we assume 50 kpc for the distance to the LMC (Westerlund 1990), and $v_{\text{helio,LMC}} = 275 \pm 4 \text{ km s}^{-1}$ as the heliocentric velocity of the LMC ISM immediately surrounding N132D (Vogt & Dopita 2011). Heliocentric velocities noted by v_{helio} have been corrected to the Solar System barycentric standard of rest. The errors quoted in the text and table represent the 90% confidence level, and the error bars given in the spectra represent 68% confidence.

2 Observations and Data Reduction

The Hitomi X-ray Observatory was launched in February 2016 and tragically lost at the end of March (Takahashi et al. 2016). During the month of operation, the SXS successfully demonstrated its in-orbit performance by achieving an unprecedented spectral resolution ($\Delta E \approx 5 \text{ eV}$) across a broad energy (2–12 keV) for extended sources (Kelley et al. 2016; Porter et al. 2016a). This led to accurate determination of the turbulent velocity of hot plasma in the Perseus Cluster by measuring the line width of the Fe xxv He α fine structure (Hitomi Collaboration et al. 2016).

After the Perseus observations, Hitomi aimed at the SNR N132D for performance verification of the SXS and SXI using another line-rich source. The other detectors, the Hard X-ray Imager (HXI) and Soft Gamma-ray Detector (SGD), were not yet turned on. Unfortunately, the satellite attitude control system lost control about 30 minutes after the observation started due to problems in the star tracker system, as illustrated in figure 1. Because of this, the SNR drifted out of the $3' \times 3'$ SXS FoV and remained out of view for the remainder of the observation. Thanks to its larger FoV, the SXI was able to observe the source during the entire observation.

As this observation took place during the commissioning phase, several instrument settings were non-standard compared to expected science operation. First, the SXS gate valve was in the closed configuration to reduce the chance of molecular contamination from spacecraft out-gassing. The gate valve had a $\sim 260 \mu\text{m}$ thick Be window to allow observations while closed, but this absorbed almost all X-rays below $\sim 2 \text{ keV}$ and reduced the effective area by $\sim 50\%$ at higher energies (Eckart et al. 2016). Thus we limit our SXS analysis to the 2–10 keV regime. Second, while the SXS was close to thermal equilibrium at this point in the commissioning phase (Fujimoto et al. 2016; Noda et al. 2016), no on-orbit, full-array energy scale (or gain) calibration had been performed with the filter-wheel calibration sources. The Modulated X-ray Source (MXS; de Vries et al. 2017) was also not available for contemporaneous gain measurement. A dedicated calibration pixel that was outside of the aperture and continuously illuminated by a collimated ^{55}Fe source served as the only contemporaneous energy-scale reference, and the time-dependent scaling required to correct its gain

was applied to each pixel in the array (Porter et al. 2016b). It was well known prior to launch that the time-dependent gain-correction function for this calibration pixel generally would not adequately correct the energy scale of the array pixels. In particular, the relationship between changes on the calibration pixel and on the array was not fixed, but rather depended on the temperatures of various shields and interfaces in the SXS dewar. Therefore, although the relative drift rates across the array were characterized during a later calibration with the filter-wheel ^{55}Fe source (Eckart et al. in prep.), changes in SXS cryocooler settings between the N132D observation and that calibration limit the usefulness of that characterization.

In fact, the measured relative gain drift predicts a much larger energy-scale offset between the final two pointings of the Perseus Cluster than was actually observed. Using source-free SXS observations taken during the period with the same cryocooler settings as the N132D observation (2016 March 7–15) in order to circumvent this limitation, we measured the center of the Mn K α instrumental line (Kilbourne et al. in prep.), and conclude that the SXS energy scale is shifted by at most $+1 \pm 0.5 \text{ eV}$ at 5.9 keV (Eckart et al. in prep.). There are no sufficiently strong low-energy lines in the same data set, but extrapolating from Perseus Cluster observations, we estimate a gain shift of $-2 \pm 1 \text{ eV}$ at 2 keV (Hitomi Collaboration, in prep. [Perseus cluster atomic data paper]). In the filter-wheel ^{55}Fe data set, errors in the position of the Mn K β line ranged from -0.6 to $+0.2 \text{ eV}$ across the array. Since this line is at 6.5 keV, less than 1 keV from the Mn K α reference line, gain errors at other energies further from the reference may be substantial. This is especially true in science data, for which drift of the energy scale can only be corrected via the data from the calibration pixel. To be conservative, we use a systematic gain error of $\pm 2 \text{ eV}$ at all energies in the analysis below.

We analyzed the cleaned event data of the final pipeline processing (Hitomi software version 6, CALDB version 7) with the standard screening for both SXS and SXI (Angelini et al. 2016), with one exception. To maximize the good SXS observing time, we relaxed the requirement that eliminates data when the aimpoint is further than $1.5'$ from the target position. Using a maximum angular offset of $2.2'$ ensures that at least 50% of the SNR is still in the FoV, and it increases the good SXS exposure time from 2,610 s to 3,737 s (by 43%) and the total SXS counts in the 2–10 keV band from 198 to 233 (by 18%). Relaxing this criterion increased the counts in the Fe xxv He α band (defined in section 3.1) from 16 to 17, and in the S xv He α band (defined in section 3.2) from 13 to 16. As we show in section 3, with the very low SXS background and very high spectral resolution, this small number of counts is sufficient to derive interesting constraints for the line centers. Some of the additional broad-band counts are from the region outside the N132D emission peak, as shown in figure 2, so they are likely background

Fig. 1. (Left) SXI images in detector coordinates showing the two OBSIDs used in the SXI analysis. The blue square shows the SXS FoV. The arrow in the left panel shows the direction N132D drifted in the focal plane during that OBSID, with black crosses marking the source center in intervals of one hour. N132D was in the SXS FoV for only 3.7 ks of OBSID 100041010, and for none of OBSID 100041020. The remnant was still visible in SXI due to that detector's larger FoV. (Right) Attitude of Hitomi during the first 7 ks of OBSID 100041010. The solid line shows ANG_DIST , the angular distance in arcmin between the intended pointing and the actual pointing. Orange bins show the good time intervals of the default data filtering, which requires $\text{ANG_DIST} < 1.5$. Blue bins show the additional $\sim 43\%$ of time added by relaxing this criterion to 2.2 . Blank times are excluded because of Earth occultation or South Atlantic Anomaly passage.

Fig. 2. Images of the SXS showing individual counts as a pixel on the sky. Blue boxes are counts included after relaxing the angular distance criterion. The red contours trace the Chandra emission, and the green circles show radii of 1.5 and 2.0 from the Chandra peak. The counts in Fe K (right) correspond well to the remnant extent, while some of the counts in the other bands are outside the bounds of the remnant.

counts. The extra counts in the lines are consistent with locations in the remnant, also shown in figure 2; in particular, to the extent that we can infer locations from the $\sim 1'$ Hitomi PSF, the S counts are found largely in the rim of the remnant, while the additional Fe K count (and all the Fe K counts) are concentrated in the remnant center, consistent with what is seen with XMM-Newton (Behar et al. 2001).

We constructed an SXS source spectrum by extracting only GRADE Hp (high-resolution primary) events from the entire SXS field of view of OBSID 100041010, and created the redistribution matrix file (RMF) with `sxsrmsf`, using the medium size option. The ancillary response file (ARF) was generated with `aharfgen`, using a high-resolution Chandra image as input to the ray-tracing. A non-X-ray background (NXB) spectrum with the same sampling of magnetic cut-off rigidity as the observation and with identical filtering as the source data (except for Earth elevation criteria) was extracted from the SXS archive NXB event file using `sxsnxbgen`. In the $2\text{--}10$ keV band, we expect 23.2 ± 0.6 NXB counts, about 10% of the observed count rate, and corresponding to ~ 0.4 counts per spectral resolution element per 100 ks. In the narrow bands used for the analysis

that follows, the NXB count rate is less than 5% of the observed rate as the SXS NXB is almost featureless and nearly constant over the energy range (Eckart et al. in prep.).

For the SXI, both OBSIDs 100041010 and 100041020 were used, although for the former we enforced the requirement that the aimpoint be within 1.5 of the target to eliminate complications in constructing a response for a source moving across the FoV. For OBSID 100041020, we used only times when the attitude was stable, although the source was not at the expected aimpoint and was partially obstructed by the chip gaps (see figure 1). The final good exposure time for the SXI was 35.4 ks.

An SXI spectrum was extracted from a 2.5 radius circle with center (RA,Dec) = $(5^{\text{h}}25^{\text{m}}02^{\text{s}}.2, -69^{\circ}38'39'')$. The NXB spectrum was produced with `sxinxngen`, using the entire SXI FoV excluding the source in order to increase the statistics. To properly scale the NXB normalization between the full FoV and source region, the instrumental lines of Au $L\alpha$ and $L\beta$ were used, producing a scaling factor of 0.0070. RMF and ARF files were generated with `sxirmf` and `aharfgen`, respectively.

3 SXS Spectral Analysis

With only 233 counts, the SXS spectrum is dominated by Poisson low-count statistics. In addition, with the SXS gate valve closed, the bright emission lines of C, O, Ne, and Mg below 2 keV are not observable. However, three emission features are easily seen in the full-band spectrum shown in figure 3, the $\text{He}\alpha$ transition features of He-like S (~ 2.45 keV), Ar (~ 3.1 keV), and Fe (~ 6.7 keV). These lines are clearly detected in previous observations dating back to BeppoSAX (Favata et al. 1997), although the combination of an extended source and lower sensitivity at these energies complicates their measurement by X-ray grating instruments like Chandra/HETGS and XMM-Newton/RGS. From narrow bands centered on each ex-

Fig. 3. Full-band SXS spectrum of N132D, showing counts with Poisson errorbars from Gehrels (1986). The orange points show the total estimated background, which has not been subtracted. Both spectra are binned to 16 eV for display purposes.

pected line centroid, the total number of counts and estimated NXB counts are 16 total (0.30 ± 0.07 NXB) counts for S XV He α ; 14 total (0.28 ± 0.06 NXB) counts for Ar XVII He α ; and 17 total (0.8 ± 0.1 NXB) counts for Fe XXV He α . The signal-to-noise of these features and the underlying continuum is insufficient to obtain useful constraints on the metal abundance, temperature, or velocity broadening of the emitting plasma. However, as we show below, given a reasonable spectral model from other sources, the exquisite spectral resolution of SXS allows us to measure the line centers and thus the average line-of-sight Doppler velocity of two of these components, S and Fe.

All spectral fitting described below was performed with XSPEC v12.9.1d (Arnaud 1996), using atomic and non-equilibrium ionization (NEI) emissivity data from AtomDB v3.0.8 (Foster et al. 2012), and abundance ratios from Anders & Grevesse (1989). In each restricted fitting region, we allowed only the line-of-sight velocity and normalization of the appropriate thermal component (described below) to vary in the initial fit. While we include the cosmic X-ray background (CXB), it is negligible; a reasonable model for the 2–10 keV contribution of the CXB power law component with $\Gamma = 1.4$, $S(2\text{--}10 \text{ keV}) = 5.4 \times 10^{-15} \text{ erg cm}^{-2} \text{ s}^{-1} \text{ arcmin}^{-2}$ (e.g., Ueda et al. 1999; Bautz et al. 2009) predicts a mean of 1.5 CXB counts across the entire band and less than 0.1 CXB counts in any of the narrow spectral analysis bands. This is less than 1% of the detected counts. Galactic foreground emission is negligible above 2 keV toward this direction ($l = 280^\circ$, $b = -32^\circ 8$).

3.1 Iron Region Spectral Analysis

Fe K emission in N132D has been explored previously (Favata et al. 1997; Behar et al. 2001; Xiao & Chen 2008; Yamaguchi et al. 2014), with the conclusion that this feature is dominated

by Fe XXV He α emission. The XMM-Newton/EPIC observations are successfully fit above 2.5 keV with a two-temperature-component model with $kT = 0.89$ and 6.2 keV (Behar et al. 2001). The cooler component produces the strong soft emission lines seen with XMM-Newton/RGS, and the hotter component explains the Fe K emission. In particular, Behar et al. (2001) emphasize the lack of a temperature component at ~ 1.5 keV to explain the lack of observed L-shell emission from Li-, Be-, and B-like Fe in the XMM-Newton spectrum. A recent study using 240 ks of Suzaku data combined with a 60 ks NuSTAR observation (Bamba et al. 2017) has produced a two-component broadband spectral model of N132D with a similar cool temperature ($kT \approx 0.8$ keV) but that interprets the Fe K emission arising primarily from an over-ionized, recombining plasma component with $kT_e = 1.5$ keV, $kT_{\text{init}} > 20$ keV, and relaxation timescale $n_e t \approx 10^{12} \text{ s cm}^{-3}$. Crucially, the Suzaku data show a clear detection of H-like Fe Ly α emission, indicating that an under-ionized (ionizing) plasma is unlikely to contribute significantly to the emission at these energies, and thus much of the otherwise unresolved Fe K emission is likely due to He-like Fe rather than lower ionization states.

These previous observations provide confidence that we know where the line centroid should be for the Fe K complex, and can cleanly measure the line-of-sight velocity. However, we emphasize that this is one possible interpretation of a plasma with strong Fe XXV He α and measurable Fe XXVI Ly α emission. A more complicated temperature structure, such as from multiple unassociated, spatially unresolved components, could produce a very different complex of lines in this spectral region. We address this possibility further in section 5. To ease comparison to current work, we adopt the model from Bamba et al. (2017) as a baseline model, shown in figure 4 and table 3.1.

The Fe XXV He α complex, shown in figure 5, was fit within the energy range 6.45–6.80 keV. This range includes sufficient width to constrain the continuum and measure velocity shifts up to $\sim 7000 \text{ km s}^{-1}$, but avoids contamination from a possible 6.4 keV Fe K line and any H-like Fe features. It is clear from figure 4 that in this very clean fitting region the model is dominated by emission from the recombining plasma component by at least a factor of 100 over the cooler collisional ionization equilibrium (CIE) component. Therefore, while we included the entire model with all components for the Fe region fit, we only allowed parameters related to the NEI component to vary. To allow for differences in the observed flux due to the smaller SXS FoV and attitude drift, we fixed the ratio of the CIE to NEI component normalizations to that derived by Bamba et al. (2017), and allowed the NEI flux to vary along with the line-of-sight velocity. The CIE component was modeled by a variable-abundance vavpec model in XSPEC, while the NEI component was modeled by a variable-abundance recom-

Fig. 4. N132D model spectrum, with contributions from individual components shown along with the total spectrum (black). All components are plotted with zero velocity and no line broadening. In the Fe XXV He α band (left), the NEI component (blue) dominates by a factor of ~ 100 over the CIE component (orange). In the S XV He α band (right), the CIE component is ~ 10 times brighter than all other components. The gray shading indicates the bands used for spectral analysis; the S region is chosen to exclude contributions from Si XIV, while the Fe region is chosen to exclude the bright neutral Fe K line (yellow) and the Fe XXVI feature, but include possible contributions from lower ionization states of Fe near 6.5 keV.

binning plasma model, *vrnei*. We included a single Gaussian broadening parameter to allow for thermal and turbulent broadening as well as unresolved bulk motion.

Parameter estimation was performed in two ways. First, maximum likelihood estimation was done by minimizing the fit statistic, using *cstat* in XSPEC, a modified Cash (1979) statistic. With the broadening width fixed at zero, this fitting revealed a highly non-monotonic parameter space for the velocity (see figure 6), likely due to the combination of low-count Poisson statistics in the data and discrete spectral features in the model. The best-fit velocity of $v_{\text{helio}} = 1440 \text{ km s}^{-1}$ is significantly larger than the value of the local LMC ISM surrounding N132D, $v_{\text{helio,LMC}} = 275 \pm 4 \text{ km s}^{-1}$ (Vogt & Dopita 2011). Allowing a free broadening width eliminated this non-monotonicity (see figure 7), resulting in a best-fit $v_{\text{helio}} = 1140 \text{ km s}^{-1}$ and broadening of $\sigma = 510 \text{ km s}^{-1}$.

Second, to fully explore parameter space, we performed Markov chain Monte Carlo (MCMC) simulations within XSPEC using Bayesian inference. These simulations were run with and without velocity broadening, using both a flat (uniform) prior distribution and a Gaussian prior distribution for the broadening width. The width of the Gaussian prior distribution was chosen to reflect current upper limits on the velocity broadening. In particular, observations with CCD-based X-ray observatories such as Suzaku (e.g. Bamba et al. 2017) have not found measurable broadening. The typical spectral resolution of such instruments near 6 keV is $\sim 150\text{--}180 \text{ eV}$ FWHM, depending on the epoch of observation, with a typical $1\text{-}\sigma$ calibration uncer-

tainty of $5\%^2$. This calibration uncertainty can be thought of as an upper limit on the detectable line broadening velocity. Since the broadening is a convolution, this extra velocity component adds in quadrature with the instrumental width. We find that a 5% increase on the $150\text{--}180 \text{ eV}$ FWHM instrumental width is equivalent to an extra broadening component with FWHM of $48\text{--}58 \text{ eV}$, or $\sigma = 900\text{--}1100 \text{ km s}^{-1}$ in the center of our fitting band. We therefore adopted 1000 km s^{-1} as a natural $1\text{-}\sigma$ width to use for the Gaussian prior distribution. We performed MCMC simulations using both the flat, uninformative prior and the weakly informative Gaussian prior.

The MCMC results are consistent with the local *cstat* minima in velocity parameter space for fits with and without broadening, as shown by the MCMC posterior probability distributions in figures 6 and 7. In particular, the complicated velocity posterior distribution shows up clearly in the MCMC runs without broadening, but with the most likely value (highest mode) near $v_{\text{helio}} = 800 \text{ km s}^{-1}$ instead of 1400 km s^{-1} as found in the *cstat* minimization. The MCMC chain steps shown in figure 6 (right) indicate that the simulation is well-behaved and samples the posterior distribution adequately despite the multimodal structure. The runs with broadening result in Gaussian posterior distributions with peak near 1000 km s^{-1} . Using either a Gaussian or Cauchy form for the chain proposal distribution produced the same results.

We used these posterior distributions to obtain central credible intervals on v_{helio} . For the fit with no broadening, a single interval is uninformative due to the complicated structure. We obtain a 68% credible interval of $730\text{--}1460 \text{ km s}^{-1}$, 90% interval of $440\text{--}1540 \text{ km s}^{-1}$, and 95% interval of $160\text{--}1620 \text{ km s}^{-1}$. A line-of-sight velocity consistent with $v_{\text{helio,LMC}}$ is ruled out at 93% confidence under this model. With broadening, a single credible interval is sufficient to characterize the Gaussian-shaped distribution, and we find 90% credible intervals of $330\text{--}1780 \text{ km s}^{-1}$ for broadening with a Gaussian prior distribution, and $0\text{--}2090 \text{ km s}^{-1}$ for a flat prior. The conservative gain uncertainty of $\pm 2 \text{ eV}$ (see section 2) produces a systematic uncertainty of $\pm 90 \text{ km s}^{-1}$, well within the statistical uncertainty. It is apparent that imposing an flat, uninformative prior on the broadening width distribution allows unrealistic values exceeding $\sigma = 3000 \text{ km s}^{-1}$ with a broad tail to very high values. This greatly exceeds the thermal width of an Fe emission feature at 2 keV ($\sigma \sim 50 \text{ km s}^{-1}$), and requires either extreme turbulence or very large bulk motions. If we adopt the results with the Gaussian prior, which has sufficient width to allow a blueshifted and redshifted component separated by up to $\sim 2000 \text{ km s}^{-1}$, a mean line-of-sight velocity consistent with $v_{\text{helio,LMC}}$ is ruled out at 91% confidence under this model. The model parameters are listed in table 3.1.

* Unless noted otherwise, values without quoted uncertainties are fixed. Uncertainties are 90% confidence limits.

[†] Results with broadening are from inference with a Gaussian prior with $\sigma = 1000 \text{ km s}^{-1}$.

[‡] Flux is given in units of $10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$. The ratio of the vapec and vrnei component normalizations was fixed to that in Bamba et al. (2017).

[§] “Goodness-of-fit” is the percentage of simulated observations with lower fit statistic than the real data, as described in section 3.1.

Fig. 6. (left) Posterior probability distributions of the $vrnei$ model normalization (orange) and velocity (blue) from the Fe K region fitting without broadening, calculated from the MCMC analysis as described in the text. Points show sample MCMC chain steps, indicating that there is no correlation between the two parameters. The black line shows the $cstat$ value from fit statistic minimization, as a function of best-fit velocity. One peak of the MCMC velocity distribution coincides with the best-fit velocity distribution, and other local peaks coincide with local $cstat$ minima, indicating both maximum likelihood methods produce the same result. The dotted lines delineate the central 90% credible interval and note the local LMC velocity. (right) MCMC chain values for the Fe K velocity plotted against chain step, showing that the long-term variations of each chain are well-behaved and the posterior distribution is well-sampled. Vertical lines differentiate the eight individual 20,000-step simulation chains. Steps within chains are in time order with one out of every ten steps shown for clarity.

Fig. 7. Posterior probability distributions of the $vrnei$ model broadening width (orange) and velocity (blue) from the Fe K region fitting including line broadening. Notations are the same as in figure 6. The left panel shows results with flat prior on the line width, while the right panel shows results imposing a Gaussian prior with $1-\sigma$ width of 1000 km s^{-1} . Both velocity distributions trace the $cstat$ minimization well. The flat prior produces a broader posterior distribution.

The measured photon flux in the fitting band, $4.6^{+2.3}_{-1.4} \times 10^{-5}$ ph cm $^{-2}$ s $^{-1}$, is more than a factor of two higher than previous estimates of the Fe K α line flux, e.g. $1.83 \pm 0.17 \times 10^{-5}$ ph cm $^{-2}$ s $^{-1}$ (Yamaguchi et al. 2014; errors are 90%). This is likely due to a combination of the Hitomi attitude uncertainty and the use of a broad-band X-ray image to produce the response files. While much of this broad-band X-ray emission is found in a shell with diameter $\sim 2'$, the Fe K α emission appears centrally concentrated (e.g., Behar et al. 2001). Using the more spatially extended broad-band image produces a lower response as some of the PSF-broadened flux falls outside of the $3' \times 3'$ SXS FOV, thereby increasing the inferred model flux for a given count rate. Our inclusion of data with large pointing offset of up to $2.2'$ and the large attitude drift undoubtedly exacerbate this effect. For this reason, the flux calibration is so uncertain that a flat, uninformative prior is a good representation of our knowledge of the SXS effective area for this observation.

Once the minimum fit statistic and parameter distribution function were determined, we explored the effects of adjusting other `vrnei` parameters within a reasonable range of uncertainty. In addition, we ran fits testing plasma models with higher over-ionization (setting n_{et} to a small value), under-ionization (an ionizing plasma, setting $kT_{\text{init}} < kT$), and collisional ionization equilibrium (CIE, setting $kT_{\text{init}} = kT$). The fit statistic was consistent in all cases, indicating that we cannot distinguish between various ionization states with the Hitomi/SXS data alone. In all cases, neither the best-fit velocity nor its posterior distribution from the MCMC analysis changed appreciably, indicating that our results are insensitive to the exact emission model used so long as it is not highly complex.

Neither the XSPEC `cstat` statistic nor the MCMC analysis provides an estimate of the goodness of fit. We used two tests available in XSPEC, Kolmogorov-Smirnov (KS) and Cramer-von Mises (CvM), both of which treat the observed and model spectra as empirical distribution functions and compute a statistical difference between the two. Drawing parameter values for velocity, normalization, and broadening width from the full posterior distributions, we performed 1000 simulations of the observed 3.7 ksec spectrum for the fits with and without broadening. These simulated spectra were then fit with the model, and the resulting KS and CvM test statistics were compared with the values from the original fits. For the fit without broadening, 24% of the realizations produced a smaller KS statistic than the best fit, and 35% produced a smaller CvM statistic. For the fits with broadening, the fractions were 20% for KS and 21% for CvM. We can only say that our best-fit models are not statistically inconsistent with the data.

Since this asymmetric velocity structure is unexpected, we constrained a potential blue-shifted emission feature by adding a second `vrnei` component with identical model parameters. The velocity of the first component was fixed to the best-fit

value of 1140 km s^{-1} , while that of the new component was fixed to -590 km s^{-1} , to force symmetry about $v_{\text{helio, LMC}}$. The `vrnei` normalizations, initially equal, were allowed to vary independently. We find that a blue-shifted feature is allowed at up to 30% of the flux of the redshifted component, with a similar fit statistic and goodness-of-fit measure. Varying the blueshift within a reasonable range did not improve the fit or change the upper limit to its flux. The best-fit broadening width ($\sigma \sim 500 \text{ km s}^{-1}$ or FWHM $\sim 1200 \text{ km s}^{-1}$) allows some blueshifted component, but the emission-weighted mean velocity is not centered on the LMC velocity. We conclude that the bulk of the He-like-iron-bearing material is receding asymmetrically, at a velocity $\sim 800 \text{ km s}^{-1}$ with respect to the swept-up ISM surrounding N132D.

3.2 Sulfur Region Spectral Analysis

Spectral fitting of the S XV He α line proceeded in a similar manner to the Fe K region. We restricted the energy range to 2.40–2.48 keV, leaving 16 total counts of which 0.30 ± 0.07 ($\sim 2\%$) are estimated to be from the NXB. Consistent with other recent work, we interpret the S XV He α emission to arise predominantly from a CIE plasma with $kT \sim 1 \text{ keV}$ (Behar et al. 2001; Borkowski et al. 2007; Xiao & Chen 2008). In our baseline model, the CIE component dominates the NEI emission by a factor of ~ 5 – 10 in this region. Thus we allowed some small contamination from the high-redshift NEI emission by freezing the velocity and broadening of the `vrnei` component to the best-fit values, and fixed the ratio of the `vapc` to `vrnei` normalizations to that found by Bamba et al. (2017). Only the velocity and normalization of the CIE `vapc` component were allowed to vary in the initial fit, but as with the Fe fit, we included broadening with similar priors to explore the effect on the derived velocity. The S region spectrum and model are shown in figure 5, posterior probability distributions are shown in figure 8, and best-fit parameters are given in table 3.1.

Using the `cstat` maximum likelihood estimator, we obtain a best-fit line-of-sight velocity of $v_{\text{helio}} = 210 \text{ km s}^{-1}$ with broadening fixed at zero. Allowing a single broadening component results in $v_{\text{helio}} = 520 \text{ km s}^{-1}$ with $\sigma = 520 \text{ km s}^{-1}$. As with the Fe fitting, the posterior distributions in figure 8 are considerably wider when broadening is included, with 90% credible intervals on v_{helio} of -170 to $+580 \text{ km s}^{-1}$ with no broadening and -100 to $+1290 \text{ km s}^{-1}$ with a Gaussian prior on broadening with $\sigma = 1000 \text{ km s}^{-1}$. Unlike for Fe, the velocity of the S component is completely unconstrained with a flat broadening prior. Our adopted SXS gain uncertainty of $\pm 2 \text{ eV}$ (245 km s^{-1} ; see section 2) is again well within this statistical uncertainty, which itself is consistent with the local LMC velocity of 275 km s^{-1} .

We performed additional spectral fitting, allowing kT of the

Fig. 8. Posterior probability distributions for the S region fit. In the left panel, vapec model broadening is fixed at zero, and the posterior model normalization is shown in orange. In the right panel, a Gaussian prior with width $\sigma = 1000 \text{ km s}^{-1}$ is imposed on the broadening, and the posterior broadening distribution is shown in orange. The velocity posterior distribution is shown in blue in both panels. Other notations are the same as in figure 6. Both velocity posterior distributions are Gaussian in shape and trace the cstat minimization well. The model with broadening produces a broader distribution shifted to higher velocity, but still consistent with the local LMC velocity.

CIE component and kT , kT_{init} , $n_e t$, and σ of the recombining plasma component to vary over a broad range as in the Fe region fitting described in the previous section. The best-fit velocity and credible intervals did not change. We performed the same goodness-of-fit tests to the S region fits as the Fe region fits, finding that 30–60% of the simulated datasets produced a smaller test statistic. The model is thus consistent with the data, and we conclude that the He-like-sulfur-bearing gas is consistent with being at rest relative to the local LMC ISM, if we assume that line broadening is small.

3.3 Argon Region Spectral Analysis

Spectral fitting of the Ar XVII He α line is complicated by both the low number of total counts (14) and the estimated contributions from both CIE and NEI components. In fact, the Ar abundance is not constrained in either component, leading to a degeneracy between the normalization and abundance in each component and further difficulty fitting different velocities. As a simple test, we fixed the vapec and vrnei normalizations to the Bamba et al. (2017) values, fixed the Ar abundance to solar for both components, and fit a single line-of-sight velocity and normalization. The best-fit velocity is $v_{\text{helio}} = 2400 \text{ km s}^{-1}$, with a 90% credible interval of 570–5900 km s^{-1} . This is consistent with both velocity ranges of Fe XXV and S XV. If the velocities are tied at the offset to the best-fit values so that $v_{\text{vrnei}} = v_{\text{vapec}} + 1200 \text{ km s}^{-1}$, the fit statistic is only slightly worse (cstat = 81.2 vs. 80.8), and the best-fit values are $v_{\text{helio}} = 1800 \text{ km s}^{-1}$ for the vrnei component and 600 km s^{-1} for the vapec, with similar uncertainties. Given the uncertainties in the model, we can only conclude that the Ar XVII fit is consistent with the Fe and S line results.

4 SXI Spectral Analysis

For the following analysis, the same version of XSPEC, AtomDB, NEI emissivity data, and abundance tables were used as in the analysis of the SXS spectrum (see section 3). The NXB-subtracted spectrum is shown in figure 9. In the N132D observation, the event and split thresholds are 600 eV and 30 eV, respectively. Since charge from a detected X-rays may be split among multiple CCD pixels, the quantum efficiency (QE) can be affected by split events well above the event threshold. Given the limited amount of calibration information available in these early observations, we conservatively exclude the energy band below 2 keV in this study.

We detect emission lines at $2.456 \pm 0.010 \text{ keV}$ and $6.68 \pm 0.04 \text{ keV}$, which correspond to the same He α lines of S and Fe detected in SXS, respectively. The SXI is affected by light leak when the satellite is in daylight, which can result in an observed line center shift (Nakajima et al. in prep.). We investigated the line center shift in the N132D data, and confirmed that daylight illumination of the spacecraft has no effect. The S XV He α line center is fully consistent with the centroid of the line complex measured with SXS (see figure 5). The Fe XXV He α line center is marginally consistent with SXS within the uncertainty (see figure 5), and likely includes some unresolved contribution from Fe XXVI Ly α at $\sim 7 \text{ keV}$ (see figure 4).

Following the SXS analysis, we adopted a spectral model with two thin-thermal plasmas, a low-temperature vapec and high-temperature vrnei. From the model of Bamba et al. (2017), we also include a 6.4 keV neutral Fe K line, a non-thermal component, and the CXB. In the SXI analysis, the normalizations of the two plasmas are set to be free and all the other thermal parameters are fixed to those of Bamba et al. (2017). The normalization of the Fe I K line was tied to that

Fig. 9. SXI spectrum of N132D. Black data points show the full spectrum, red show the scaled NXB spectrum, and blue show the NXB-subtracted spectrum. Emission over the background is clearly seen above 10 keV.

of the *vrnei* component using the ratio of normalizations from Bamba et al. (2017). A power-law model was added for the possible non-thermal component, with both photon-index Γ and normalization allowed to vary. For the CXB, another power-law model with fixed parameters of $\Gamma = 1.4$ and surface brightness $5.4 \times 10^{-15} \text{ erg cm}^{-2} \text{ s}^{-1} \text{ arcmin}^{-2}$ in the 2–10 keV band was used (Ueda et al. 1999; Bautz et al. 2009). This CXB intensity is expected from observations with previous X-ray imaging instruments with similar PSF, and thus similar confusion limits. Since we are in the high-counts regime with at least 30 counts per spectral bin in the total (unsubtracted) source spectrum and high statistics in the NXB spectrum, we expect the background-subtracted spectral bins to be Gaussian distributed and use χ^2 minimization. We obtain $\chi^2/\text{d.o.f.} = 234/243$ and an acceptable fit at the 90% confidence level. The best-fit model with individual components is shown in figure 10. To check for potential bias in the use of χ^2 statistics, we perform the fit again excluding the poorest statistical region above 9 keV, and obtain similar results.

The lower and higher temperature plasmas produce the majority of the He α lines of S and Fe, respectively, consistent with the result of the previous study (see also figure 4). The best-fit *vaptec* normalization was 0.92 ± 0.03 of the value from Bamba et al. (2017), while the *vrnei* was 0.86 ± 0.10 of their best-fit value. The model fitting results in a non-thermal component with flux $1.3 \pm 1.1 \times 10^{-13} \text{ erg cm}^{-2} \text{ s}^{-1}$ in the 2–10 keV band. If we assume this non-thermal component exists, the fit constrains the photon index to be $\Gamma < 3.0$. With the SXI data in hand, we are unable to say conclusively that the non-thermal component is required, only that it is consistent with the observed spectrum.

Fig. 10. SXI spectrum of N132D fitted with the model discussed in the text, with individual components shown. Two thin-thermal plasma components are shown with orange (*vaptec*) and red (*vrnei*) lines. The 6.4 keV Fe K line is shown in blue, the CXB power law component in green, and the marginally detected non-thermal component in magenta.

5 Discussion

We have revealed a significant redshift of the emission lines of He-like Fe, constraining the line-of-sight velocity to be $\sim 1100 \text{ km s}^{-1}$, or $\sim 800 \text{ km s}^{-1}$ faster than the local LMC ISM. The emission of S xv He α , on the other hand, shows a velocity consistent with the radial velocity of the LMC ISM, albeit with large uncertainty, especially when broadening is included in the model. These results suggest different origins of the Fe and S emission: the former is dominated by the fast-moving ejecta and the latter by the swept-up ISM. This interpretation is consistent with the previous work by XMM-Newton, which revealed that the Fe emission has a centrally-filled morphology and the S emission is found along the outer shell (Behar et al. 2001).

This interpretation hinges on our assumed underlying emission model. Previous results from XMM-Newton (Behar et al. 2001) and the detection of an Fe xxvi Ly α line in the Suzaku spectrum (Bamba et al. 2017) suggest minor contamination from lower-energy, lower-ionization states of Fe. It is possible that the H-like Fe emission arises from a much hotter plasma that does not produce He-like emission, and the Fe K complex in question is produced by lower-temperature plasma unresolved by both the Suzaku and Hitomi PSF. Although L-shell lines of lower-ionization Fe were not detected by (Behar et al. 2001), it is further possible that the L-shell energy band is dominated by the low temperature swept-up ISM component, hindering detection of faint ejecta lines. We are unable to conclusively demonstrate the validity of our assumptions with existing X-ray data, and we stress that the discussion that follows assumes the Fe K emission is dominated by He-like Fe.

The best-fit broadening widths for both Fe K and S K, $\sigma \sim 500 \text{ km s}^{-1}$, greatly exceed thermal broadening at these temperatures. It is unclear whether the constraints on broaden-

ing are physical or somehow related to the combination of low statistics and complicated line structure in the thermal model. The addition of broadening simplifies the posterior velocity distribution without greatly changing the 90% credible interval, and we can speculate that if this line broadening is physical, there could be Fe K-emitting material at a range of velocities due to bulk motion, including very high ones. Much better statistics at similar spectral resolution are required to further understand the velocity structure in both Fe K and S K.

These Fe-rich ejecta display very different line-of-sight velocity structure compared to the O-rich ejecta explored in detail in the optical. The O-rich ejecta traced by [O III] $\lambda 5007$ emission have an average blueshifted velocity of $\sim -500 \text{ km s}^{-1}$ with respect to the local LMC when an elliptical shell model is fit in projected space and velocity (Morse et al. 1995). Vogt & Dopita (2011) confirm this systematic offset, but point out that the complicated spatial structure of the ejecta heavily biases the average velocity of the emission as different clumps interact with the reverse shock at different times. The ring structure of the O-rich ejecta first suggested by Lasker (1980) and confirmed in several successive studies is possibly accompanied by a polar jet associated with a “run-away” knot and the enhanced X-ray emission along the southwestern shell (Vogt & Dopita 2011). It is tempting to speculate that the Fe emission is associated with such a jet, but a more significant detection at higher spatial resolution is required.

The lack of blue-shifted emission indicates a highly asymmetric distribution of the Fe-rich ejecta. Such asymmetry is seen morphologically in the ejecta of other core-collapse SNRs, such as Cas A (Grefenstette et al. 2017), G292.2+1.8 (Bhalerao et al. 2015), and W49B (Lopez et al. 2013a), and in the more evolved SNRs dominated by shocked ISM/CSM but with Fe knots such as Puppis A (Hwang et al. 2008; Katsuda et al. 2008; Katsuda et al. 2013). Notably, the Fe ejecta in these remnants are not always centrally concentrated, as would be expected in a typical core-collapse explosion. In Cas A, the mismatch between the shocked Fe ejecta and more concentrated, redshifted ^{44}Ti has been interpreted in light of the SN explosion mechanism involving instabilities such as SASI (Grefenstette et al. 2017). N132D is more evolved than Cas A and perhaps better compared to W49B, with which it is comparable in age. The X-ray morphology of N132D is more symmetric than W49B, and relatively symmetric among core-collapse SNRs in general (Lopez et al. 2011), despite the obvious differences between the bright southern shell and the blown-out northeastern region. This symmetry could indicate a projection effect and an axis of symmetry along the line-of-sight. If N132D were observed perpendicular to the direction it is, it might appear more highly asymmetric, like W49B.

The origin of the over-ionized plasma is not completely clear. Interestingly, both N132D and W49B show evidence for

overionization of the Fe ejecta (Ozawa et al. 2009; Bamba et al. 2017), suggesting a possible connection between asymmetric ejecta distribution and overionization. In addition, recombining plasma is observed in several mixed-morphology SNRs that are interacting with molecular clouds (e.g., Yamaguchi et al. 2009; Uchida et al. 2015); although the mechanism responsible for the peculiar plasma conditions in these remnants is still unclear, a possible connection is the inhomogeneous medium into which the SNR is expanding. In N132D, the entire southern half of the remnant is surrounded in projection by molecular gas, with Mopra 22-m telescope CO data showing that the outer shell is sweeping through the cloud (Banas et al. 1997; Sano et al. 2015). This molecular gas distribution combined with the X-ray emission morphology showing a brighter shell impinging on the cloud in the south suggest that the shock is slowing here due to the cloud, while the fainter shell blowing out toward the north and northeast suggests that the shock is expanding faster here. The detection of both GeV emission (Ackermann et al. 2016) and neutral Fe K (Bamba et al. 2017) from N132D further suggest that accelerated protons are interacting with the nearby molecular cloud (Bamba et al. 2017). It is likely that N132D is expanding into a highly inhomogeneous medium.

In W49B, the recombining plasma is detected on the west side of the remnant whereas the molecular cloud is to the east, suggesting that the dominant cooling mechanism producing the over-ionized plasma is rapid expansion of the inner ejecta (Miceli et al. 2010; Lopez et al. 2013a). A similar density gradient is apparent in N132D, however due to the insufficient spatial resolution of either Suzaku or Hitomi we are unable to identify exactly where the recombining plasma is located. Comparing the Fe K map from XMM-Newton (figure 4a of Behar et al. 2001) with the molecular gas map (figure 1b of Sano et al. 2015), we see that the Fe K peak is not in the center of the remnant nor toward the blown-out low-density northeast region, but offset closer to the bright southeastern shell. Since the recombining Fe XXV $\text{He}\alpha$ is the brightest feature seen in this spectral region, this hints that the over-ionized plasma is located near the molecular cloud. With the data currently in hand, and with likely projection effects along the line-of-sight, a firm conclusion is not possible.

It was unfortunate that the first microcalorimeter observation of a thermally dominated SNR was not fully performed due to an attitude control problem. However, this short-exposure observation of N132D demonstrates the power of high-spectral-resolution detectors by detecting clear emission features with extremely low photon counts—a similarly short CCD observation would not have detected these features, let alone placed interesting constraints on the velocity. The very low SXS background of ~ 1 event per spectral resolution element per 100 ks is also vital for this result, and it opens the possibility of using slew observations for similar science with similar future instru-

ments. For N132D, revealing the Fe ejecta line-of-sight velocity structure, along with its detailed spatial distribution and proper motion, is a vital step to determine its three-dimensional velocity. Future observations with the X-ray Astronomy Recovery Mission (XARM) microcalorimeter, identical in performance to that on Hitomi, will be sufficient to spatially resolve the remnant into two regions and explore in detail the line-of-sight velocity and ionization state for each element. Observations with Athena (Nandra et al. 2013) will also be crucial to more accurately constrain the kinematics and ionization state of this SNR.

6 Conclusions

In this paper, we have presented observations of the LMC SNR N132D taken with Hitomi. Using only a short, 3.7 ks observation with the SXS, we detect emission lines of Fe XXV and S XV He α with only 17 and 16 counts, respectively. Assuming a plausible emission model and prior on the velocity broadening, the Fe line shows a redshift of 800 km s^{-1} (50–1500 km s^{-1} 90% credible interval) compared to the local LMC ISM, indicating that it likely arises from highly asymmetric ejecta. The S line is consistent with the local LMC standard of rest, shifted by -65 km s^{-1} (-450 to $+435 \text{ km s}^{-1}$ 90% credible interval) assuming no broadening, and likely arises from the swept-up ISM. Longer SXI observations produce results consistent with a recent combined Suzaku+NuSTAR spectral analysis, including a recombining thermal plasma component responsible for the Fe XXV He α emission and constraints on a non-thermal component that dominates at high energies (Bamba et al. 2017). In addition to this first result on SNRs with a microcalorimeter, the observations highlight the power of high-spectral-resolution X-ray imaging instruments in even short exposures.

Author contributions

E. Miller and H. Yamaguchi led this study and wrote the final manuscript along with S. Katsuda, K. Nobukawa, M. Nobukawa, S. Safi-Harb, and M. Sawada. E. Miller, T. Sato, M. Sawada, and H. Yamaguchi performed the SXS data reduction and analysis. K. Nobukawa and M. Nobukawa performed the SXI data reduction and analysis. C. Kilbourne contributed estimates and discussion of the SXS gain uncertainty. A. Bamba contributed the detailed spectral model used for both the SXS and SXI analysis. M. Sawada contributed to optimizing the SXS data screening. K. Mori contributed analysis of the SXI light leak. L. Gallo, J. Hughes, R. Mushotzky, C. Reynolds, T. Sato, M. Tsujimoto, and B. Williams contributed valuable comments on the manuscript. The science goals of Hitomi were discussed and developed over more than 10 years by the ASTRO-H Science Working Group (SWG), all members of which are authors of this manuscript. All the instruments were prepared by joint efforts of the team. The manuscript was subject to an internal collaboration-wide review process. All authors reviewed and approved the final version of the manuscript.

Acknowledgments

We thank the support from the JSPS Core-to-Core Program. We acknowledge all the JAXA members who have contributed to the ASTRO-H (Hitomi) project. All U.S. members gratefully acknowledge support through the NASA Science Mission Directorate. Stanford and SLAC members acknowledge support via DoE contract to SLAC National Accelerator Laboratory DE-AC3-76SF00515. Part of this work was performed under the auspices of the U.S. DoE by LLNL under Contract DE-AC52-07NA27344. Support from the European Space Agency is gratefully acknowledged. French members acknowledge support from CNES, the Centre National d'Études Spatiales. SRON is supported by NWO, the Netherlands Organization for Scientific Research. Swiss team acknowledges support of the Swiss Secretariat for Education, Research and Innovation (SERI). The Canadian Space Agency is acknowledged for the support of Canadian members.
