The Evolution of Fangs, Venom, and Mimicry Systems in Blenny Fishes

Graphical Abstract

Highlights

- Fangblennies evolved venom glands after the origin of their canine delivery system
- The venom contains toxins that have evolved convergently in other venomous lineages
- The defensive venom is multifunctional and exerts potent hypotensive effects
- Venom appears to have stimulated the evolution of numerous mimetic relationships

In Brief
Venomous animals serve as models for a variety of mimicry types. Casewell et al. find that fangblennies evolved venom after the origin of their venom-delivering fangs. The venom is potently hypotensive and is effective at protecting from predators. Its origin has seemingly stimulated an array of Batesian mimetic relationships with other fishes.

SUMMARY

Venom systems have evolved on multiple occasions across the animal kingdom, and they can act as key adaptations to protect animals from predators [1]. Consequently, venomous animals serve as models for a rich source of mimicry types, as non-venomous species benefit from reductions in predation risk by mimicking the coloration, body shape, and/or movement of toxic counterparts [2–5]. The frequent evolution of such deceitful imitations provides notable examples of phenotypic convergence and are often invoked as classic exemplars of evolution by natural selection. Here, we investigate the evolution of fangs, venom, and mimetic relationships in reef fishes from the tribe Nemophini (fangblennies). Comparative morphological analyses reveal that enlarged canine teeth (fangs) originated at the base of the Nemophini radiation and have enabled a micropredatory feeding strategy in non-venomous Plagiotremus spp. Subsequently, the evolution of deep anterior grooves and their coupling to venom secretory tissue provide Meiacanthus spp. with toxic venom that they effectively employ for defense. We find that fangblenny venom contains a number of toxic components that have been independently recruited into other animal venoms, some of which cause toxicity via interactions with opioid receptors, and result in a multifunctional biochemical phenotype that exerts potent hypotensive effects. The evolution of fangblenny venom has seemingly led to phenotypic convergence via the formation of a diverse array of mimetic relationships that provide protective (Batesian mimicry) and predatory (aggressive mimicry) benefits to other fishes [2, 6]. Our results further our understanding of how novel morphological and biochemical adaptations stimulate ecological interactions in the natural world.

RESULTS AND DISCUSSION

Fishes of the tribe Nemophini, known as fangblennies, represent a unique system for studying the adaptations underpinning the formation of mimetic relationships. This tribe consists of five genera: the venomous genus Meiacanthus and four non-venomous genera, of which Plagiotremus and Petroscirtes contain species that mimic the aposematic coloration and behavior of Meiacanthus [2, 6] (Figure 1A). A number of fangblenny models are mimicked by multiple sympatric fish species.
We first reconstructed the evolutionary relationship of fangblennies by sequencing five molecular markers from representative Nemophini species (Table S1). Our concatenated dataset (n = 36; 2,691 bp) produces a strongly supported tree topology (Figure S1) largely consistent with that of Hundt et al. [9]. However, in our tree the venomous genus *Meiacanthus* forms a strongly supported sister clade to a monophyletic group containing the genera *Aspidontus* and *Petroscirtes* (Figure 1B), whereas in Hundt et al. [9] *Meiacanthus* was found sister to *Petroscirtes* and *Xiphasia* without strong support. In our analysis, the remaining genera, *Xiphasia* and *Petroscirtes*, form a monophyletic group sister to that of *Meiacanthus*, *Aspidontus* and *Petroscirtes*.

We next used micro-computed tomography (microCT) scanning, stacking microscopy, and histology to provide a comprehensive overview of the oral morphology of fangblennies and their close relatives. Our comparative morphological analyses demonstrate that all fangblennies have enlarged canine teeth (fangs) on their lower jaw and buccal epithelium surface areas in comparison with their relatives (Figures 2, 3A, 3B, S1, and S2). Histological analyses reveal that all members of the Nemophini have hollow fangs, and while *Meiacanthus* and *Petroscirtes* both have a maxillary sheath to accommodate the enlarged teeth, only *Meiacanthus* spp. possess anterior grooves for the transmission of venom. Similarly, only *Meiacanthus* spp. have venom glands (Figures 2, 3C, and 3D). Three-dimensional reconstructions of histological sections of *M. grammistes* and *M. reticulatus* venom glands show that they surround the base of the fangs posteriorly and enter the anterior groove, an arrangement which presumably facilitates the transmission of venom from the venom gland into the target during biting (Figures 3E and 3F).

Overlaying the presence or absence of (1) enlarged canine teeth and (2) venom glands onto the species phylogeny revealed a single most parsimonious explanation for the origin of each of these characters, namely, the combined presence of enlarged canines at the base of the tribe Nemophini, and venom glands at the base of the *Meiacanthus* radiation (Figure 1B). Therefore, unlike venomous snakes where the chemical weapon preceded the refined venom delivery dentition [10], fangblennies evolved mechanical structures amenable for venom delivery prior to the origin of their toxic secretions.

Little is known about the fangblenny venom system, other than that enlarged canine teeth deliver venom into aggressors to prevent ingestion [11–14]. The defensive nature of the venom is perhaps best evidenced by observations of multiple predatory fishes ingesting *M. atrodorsalis* before “quivering of the head with distention of the jaws and operculi” occurred, followed by the fangblenny emerging from the mouth unharmed [13]. Furthermore, feeding experiments with *M. atrodorsalis* demonstrated that when their canine fangs were removed, fangblennies were readily consumed by predatory fish, whereas fangblennies with fangs intact were expelled and avoided in subsequent encounters [13].

The oral venom system of *Meiacanthus* is exceptional among teleosts, as venom is typically delivered via the mechanical rupture of secretory cells associated with dorsal and/or opercular spines [15]. Indeed, the use of an oral venom system exclusively for defensive purposes is unusual in the animal kingdom. We suggest that the absence of large fin spines amenable for effective venom delivery in blenny ancestors, coupled with the

(A) Examples of venomous *Meiacanthus* fangblennies (red circles) serving as models in mimetic relationships with other non-venomous fangblennies (orange circles) and non-fangblenny species (black circles). These relationships include Batesian and aggressive mimicry [2, 6, 7]. Photos courtesy of Rudie Kuiter, Arthur Bos, Richard Smith (© Richard Smith | OceanRealmImages.com), and K.L.C. (B) Schematic topology of the relationship between different genera found in the tribe Nemophini (see also Figure S1 and Table S1) and the single most parsimonious timings for the origin of enlarged canine teeth (fangs) and venom. Numbers at nodes represent Bayesian posterior probabilities, and asterisks (*) indicate genera that contain at least one member known to mimic *Meiacanthus* fangblennies [2].
enlargement of canine fangs, has facilitated the evolution of oral venom observed in *Meiacanthus*. Eels of the genus *Monogononthus* are the only other fishes thought to have a venomous bite [15], although they are thought to use their venom primarily for predatory purposes. Nonetheless, we note that ancestors of these fishes also lack large fin spines suitable for defensive purposes [16], suggesting an element of constraint.

To investigate the toxin composition of fangblenny venom, we constructed transcriptomes from the venom gland of *M. atrodorsalis* and tissue from the corresponding location in the non-venomous species *Plagiotremus tapeinosoma*, and we performed proteomic analyses on venom extracted from *M. grammistes* (Figure 4A). Putative toxins were identified by their abundant expression in the venom gland transcriptome and their absence, or low-level expression, in the control transcriptome, coupled with their detection in secreted venom. While many of the proteomic matches were to genes encoding constitutive housekeeping proteins, we found three toxin types, none of which have been previously reported from fish venom, that exhibit characteristics consistent with venom-specific roles: group X phospholipases A₂ (PLA₂), proenkephalin, and neuropeptide Y (Figure S3).

Proenkephalin and neuropeptide Y were both found to be expressed in the *M. atrodorsalis* venom gland transcriptome, identified proteomically in *M. grammistes* venom, and completely absent from the *P. tapeinosoma* control transcriptome, strongly suggesting venom-specific roles. Although genes encoding group X PLA₂s were detected in both transcriptomes, the expression level observed in the *P. tapeinosoma* control transcriptome was extremely low (0.04%). In contrast, both PLA₂ and neuropeptide Y were heavily expressed in the venom gland transcriptome, with single contigs representing the third and fourth most abundant annotated contigs (1.30% and 1.00% respectively; Table S2), whereas proenkephalin exhibited a more moderate expression level (0.15%; 69th most abundant).

Secreted PLA₂s hydrolyze ester bonds of glycerophospholipids to produce fatty acids and lysophospholipids, and they are common constituents in animal venoms (e.g., bees, scorpions, snakes [17]). Although the group X class of PLA₂s has not been previously described from any venom, they are known to promote inflammatory pathology [18, 19]. Using a fluorescence in vitro enzyme assay, we demonstrated that fangblenny venom exhibits considerable PLA₂ activity and causes dose-dependent cleavage of a PLA₂-specific substrate (Figure 4B).
To put these results into biological context, we compared the PLA2 activity of fangblenny venom with those of two viperid snakes \( (Tropidolaemus\ wagleri)\) and \( (Parias\ hageni)\) known to have venom PLA2s\[20, 21\]. We found comparable levels of substrate cleavage between the different venoms (Figure 4B), suggesting that fangblenny PLA2 is likely a biologically relevant venom toxin.

Proenkephalin encodes multiple 5-aa peptides known as met-enkephalins, which are endogenous opioid hormones that function by interacting with opioid receptors and induce transient analgesia, hypotension, and inflammatory responses\[22–24\]. To test for opioid activity, we screened fangblenny venom against human embryonic kidney 293 (HEK) cells expressing \( \mu, \kappa, \) and \( \delta \)-subtype opioid receptors. The \( \delta \) and \( \mu \), but not \( \kappa \), displayed significant inhibition of cAMP production in the presence of fangblenny venom, with the greatest reduction seen with the \( \delta \) cell line (Figures 4Ca and S4). To confirm that the inhibition of cAMP observed in the \( \delta \) and \( \mu \) cells was mediated through the opioid receptors, we used naloxone, a non-selective opioid receptor antagonist, to block receptor activity. We find that the inhibited production of cAMP caused by fangblenny venom was largely blocked by naloxone in cells expressing \( \delta \)-subtype opioid receptors, but not in those expressing \( \mu \) (Figures 4D and S4). These results demonstrate that, in a similar manner to those identified from the venom of the scorpion \( B.\ martensii \)[25], enkephalin peptides found in \( Meiacanthus \) induce physiological effects via their interaction with \( \delta \)-subtype opioid receptors.

Consequently, we assessed the bioactivity of fangblenny venom in in vivo cardiovascular assays. We found that \( M.\ grammistes \) venom caused a marked depressor effect on the mean arterial pressure of anaesthetized rats (Figure 4E), consisting of a transient depressor response followed by a sustained depressor response and resulting in a maximal decrease of 37% (±5%). Despite this potent hypotensive bioactivity, we found that \( M.\ grammistes \) venom had no significant effect on the heart rate of anaesthetized rats (Figure 4F). These results are highly suggestive in regards to neuropeptide Y and enkephalins: both peptides, detected here in fangblenny venom, have previously been demonstrated to significantly reduce blood pressure in vivo, without having any discernible effect on heart rate\[23, 28\].

Given prior reports of some fish venoms exhibiting neuronal bioactivity\[29\], we next tested the neurotoxic effect of fangblenny venom in the chick biventer cervicis nerve muscle (CBCNM) preparation. \( M.\ grammistes \) venom exhibited a weak neurotoxic effect by causing a significant decrease in indirect twitches of the CBCNM over 60 min (Figure 4G) but did not inhibit responses to exogenous acetylcholine, carbachol, or potassium chloride, indicating a lack of activity at skeletal muscle nicotinic receptors (Figure 4H). It remains unclear which component(s) in fangblenny venom are responsible for causing this neurotoxic bioactivity, although we note that some PLA2s found in snake venom have previously been described to cause neurotoxicity\[30, 31\].

Neuropeptide Y provides another example of the same starting substrate being convergently utilized for a role in animal venom, having previously been identified in the cone snail \( Conus\ betulinus \)[26]. These peptides are relatively well conserved, are found widely distributed in nervous systems, and are crucial for the regulation of cardiovascular processes such as blood pressure\[27\].
Spine-delivered fish venoms are typically notoriously painful, and the primary pathology observed following envenomings is pain disproportionate to the wound [29, 32]. Considering that such fish use their venom for defensive purposes, pain is an effective tool for deterring predators and invoking learned avoidance responses. Consequently, the use of pain-inducing molecules has evolved convergently in many other venomous lineages that use venom for defensive purposes [1, 33]. However, when we subcutaneously injected fangblenny venom into the hindpaw of anaesthetized mice, we observed no evidence of behavioral characteristics consistent with pain (paw lifts, licks, shakes, and flinches) and no difference between envenomed and control animals. These data correlate with some reports of human bites by fangblennies being relatively painless [13]. Therefore, in contrast to the spine-delivered venom employed by most venomous fish, we find that the oral venom of the fangblenny does not induce immediate, substantial pain to mammals. While species-specific nociceptive effects are possible, our data suggest that this defensive venom is surprisingly multifunctional, being markedly hypotensive (via neuropeptide Y and/or enkephalins), weakly neurotoxic (unknown components, possibly PLA2s), and perhaps also proinflammatory (PLA2s and/or enkephalins). The combination of these venom bioactivities therefore appears sufficient to effectively confer distastefulness and learned avoidance behaviors in piscine predators [13], perhaps irrespective of any potent nociceptive effect. Indeed, the pronounced hypotensive effects induced by venom peptides seem highly likely to affect the coordination and/or swim

Figure 4. The Bioactivity of Venom from the Fangblenny *Meiacanthus grammistes*

(A) Reduced SDS-PAGE profile of extracted venom. (B) Fangblenny venom (0.5 and 1.0 μg) exhibits dose-dependent phospholipase activity via the cleavage of a PLA2-specific fluorescent substrate. Venom PLA2 activity is comparable to that of the snakes *Paras hageni* (Hagen’s pit viper) and *Tropidolaemus wagleri* (Wagler’s pit viper) (*p ≤ 0.01; unpaired t test). See also Figure S3 and Table S2 for information on fangblenny PLA2. (C and D) Fangblenny venom (10.0, 1.0, and 0.1 μg/ml) significantly inhibits cAMP production (**p ≤ 0.001, ***p ≤ 0.001, **p ≤ 0.01, *p ≤ 0.05; one-way ANOVA with a Dunnett post-test) in HEK cells expressing δ-subtype opioid receptors (C), which was blocked by the non-selective opioid receptor antagonist naloxone (50 μM) (**p ≤ 0.0001, two-way ANOVA with a Sidak post-test) (D). See also Figure S4. (E and F) Venom (50 μg protein/kg i.v.; n = 3) causes a single depressor effect on the mean arterial blood pressure of the anaesthetized rat (E) but has no significant effect on heart rate (50 μg protein/kg i.v.; n = 3) (F). (G and H) Fangblenny venom (2.5 μg protein/ml, n = 4) induces a significant decrease (*p ≤ 0.01; unpaired t test) in the indirect twitches in the CBCNM preparation over 60 min (G) but has no effect on the responses to the exogenous agonists acetylcholine (ACh; 1 mM), carbachol (CCh; 20 μM), and potassium chloride (KCl; 40 mM) (H).

All data points represent mean ± SEM.
performance of envenomed fishes and therefore likely confer a fitness advantage to the fangblenny by facilitating escape from predators.

The evolution of venom in *Meiacanthus* fangblennies appears likely to have been a contributing factor to many other nonvenomous fish coevolving similar aposematic color patterns and swimming behaviors, thus becoming Batesian mimics and benefiting from reduced predation pressures [2, 6, 7, 34]. These putative mimics include other fangblennies (e.g., *Petrosicrates breviceps* and *Plagiotremus* spp.) and a variety of other distantly related fish (e.g., the combtooth blenny *Ecsenius gravieri* and the cardinalfish *Chelidonotus nigrotaeniatus*) (Figure 1A). Moreover, the evolution of enlarged fangs in the tribe Nemophini appears to have also stimulated a unique micropredatory feeding strategy in the genus *Plagiotremus* as, to our knowledge, all species in this genus feed by attacking larger reef fishes to access dermal tissue, scales, mucus, and fins [35, 36]. For a number of species, micropredation is facilitated by resembling venous *Meiacanthus* fangblennies—mimicry provides increased access to these resources, and thus interactions between *Meiacanthus* and *Plagiotremus* represent one of the few described examples of Batesian-aggressive mimicry [2, 6].

In summary, venomous animals provide some of the most striking examples of functional convergence, relating to their diverse yet often similar biochemical phenotypes [1]. In addition, they serve as models for a rich source of mimicry types that span the full range of mimetic relationships, from Batesian (e.g., coral snakes [5]) to Müllerian (e.g., neotropical catfish [3]) to aggressive (e.g., fangblennies [6]). Herein we characterized the venom system of *Meiacanthus* fangblennies to understand how the evolution of toxicity has facilitated the evolution of novel mimicry types and, consequently, has stimulated a variety of mimetic interactions with a diverse array of other fishes via the process of convergence. Revealing the toxic basis of these classical vertebrate mimicry models furthers our understanding of how genotypic and morphological adaptations result in phenotypic novelty, which in turn stimulate new ecological interactions in the natural world.

**EXPERIMENTAL PROCEDURES**

For complete experimental procedures, please see the Supplemental Experimental Procedures.

**Phylogenetic Reconstruction**

We extracted genomic DNA from 36 specimens of 11 species of blenny (Table S1) and used a PCR and Sanger sequencing approach to sequence two mitochondrial (12S and 16S) and two nuclear (MYH6 and PTR) markers. The resulting sequence data were aligned and concatenated into a single partitioned dataset (n = 36; 2,691 bp), and a species tree was reconstructed using Bayesian inference [37] (10 × 10⁶ generations) with optimized models of sequence evolution implemented (GTR+G for mitochondrial genes and HKY+G for nuclear genes).

**Imaging and Histology**

We scanned representative blennies (Table S1) with micro-CT (Skyscan 1076) at 9 μm and 16.6 μm (*M. grammistes* cranial reconstructions) resolution and reconstructed the scans in 3D using ImageJ v1.51f, Materialise Mimics v19.0, and MeshLab v1.3.3. The lower jaws of one specimen per species were also dissected and analyzed with a Zeiss stacking microscope, and photographs were taken using an AxiosCam MRc5 (Zeiss). For histology, dissected blenny heads were first decalcified and processed for paraffin histology using Histo-Clear as the intermediate reagent. Heads were serially sectioned at 7 μm (transverse) and stained with Mayer’s hematoxylin, 1% eosin, and 1% Alcian blue in 2.5% acetic acid. 3D reconstructions were made in Amira v5.3.3 (FEI Visualization Sciences Group).

**Transcriptomics**

Venom glands and corresponding lower jaw tissue were dissected and pooled from ten specimens each of *M. atrodorsalis* and *P. tapeinosoma*. We generated transcriptomes as described previously [38] and assembled the resulting 2.56 (M. atrodorsalis) and 3.08 (P. tapeinosoma) million 250 bp paired-end reads using Trinity v2.1.1.

**Proteomics**

We extracted venom from the fangblenny *M. grammistes* and characterized the protein profile using one-dimensional SDS-PAGE under reducing conditions with 20 μg of venom. To identify proteins present in venom, we used shotgun sequencing approaches that we previously validated [38]. Protein mass spectra were analyzed with ProteinPilot v4.0 (AB Sciex) and peptides identified via BLAST searching the UniProt database and our translated transcriptome databases.

**Bioactivity**

All animal experimentation was undertaken with approval from the University of Queensland (B.G.F., I.V.), Melbourne University (B.G.F.), and Monash University (W.C.H.) animal ethics committees. We tested for continuous PLA2 enzymatic activity in venom (0.5 and 1.0 μg) using the EnzChek Phospholipase A2 Assay Kit protocol (Thermo Fisher Scientific) and triplicate measurements over 100 cycles. An AlphaScreen CAMP assay was used to determine the activity of fangblenny venom (10.0, 1.0, and 0.1 μg/ml) on opioid receptors (μ, δ, and κ) and was performed as described previously [39], by stimulating with forskolin (80 μM) and with and without naloxone (50 μM) present. We tested the pain-inducing activity of fangblenny venom by subcutaneously injecting 20 μg of venom (1 μg/ml saline solution) into the left hindpaw of anaesthetized mice (n = 3) and monitoring pain behaviors (paw lifts, licks, shakes, and flinches) for 15 min in comparison with control animals injected with saline. The effect of venom (50 μg protein/kg) on blood pressure and heart rate was examined in anaesthetized rats (n = 3) as described previously [40]. Responses to venom were expressed as percentage changes from the pre-venom baseline. Neurotoxic venom effects were examined using the previously described CBCNM preparation [31, 40], and we monitored the effect of venom (2.5 μg/ml) on indirect twitches (n = 4) and responses to exogenous acetylcholine (ACh; 1 mM), carbamylc (CCh; 20 μM) and potassium chloride (KCl; 40mM). Responses were expressed as percentages of pre-venom addition.

**Data Resources**

DNA sequence data have been submitted to the nucleotide database of GenBank: KY020158–KY020235. Raw sequence data have been submitted to the sequence read archive (SRA) database of GenBank with the BioProject number PRJNA347283. The assembled transcriptome contigs and an Excel datasheet detailing the proteomic data and annotations have been published in Mendeley Data and are available at http://dx.doi.org/10.17632/cj2x496wp4.1.

**SUPPLEMENTAL INFORMATION**

Supplemental Information includes four figures, two tables, and Supplemental Experimental Procedures and can be found with this article online at http://dx.doi.org/10.1016/j.cub.2017.02.067.

**AUTHOR CONTRIBUTIONS**

wrote the manuscript with assistance from B.G.F. and input from all other authors.
