Decrease in scale invariance of activity fluctuations with aging and in patients with suprasellar tumors

ABSTRACT
Motor activity in healthy young humans displays intrinsic fluctuations that are scale-invariant over a wide range of time scales (from minutes to hours). Human postmortem and animal lesion studies showed that the intact function of the suprachiasmatic nucleus (SCN) is required to maintain such scale-invariant patterns. We therefore hypothesized that scale invariance is degraded in patients treated for suprasellar tumors that compress the SCN. To test this hypothesis, we investigated 68 patients with nonfunctioning pituitary macroadenoma and 22 patients with craniopharyngioma, as well as 72 age-matched healthy controls (age range 21.0–70.6 years). Spontaneous wrist locomotor activity was measured for 7 days with actigraphy, and detrended fluctuation analysis was applied to assess correlations over a range of time scales from minutes to 24 h. For all the subjects, complex scale-invariant correlations were only present for time scales smaller than 1.5 h, and became more random at time scales 1.5–10 h. Patients with suprasellar tumors showed a larger decrease in correlations at 1.5–10 h as compared to healthy controls. Within healthy subject, gender and age >33 year were associated with attenuated scale invariance. Conversely, activity patterns at time scales between 10 and 24 h were significantly more regular than all other time scales, and this was mostly associated with age.

In conclusion, scale invariance is degraded in healthy subjects at the ages of >33 year as characterized by attenuation of correlations at time scales 1.5–10 h. In addition, scale invariance was more degraded in patients with suprasellar tumors as compared to healthy subjects.

Introduction
Although our daily movements might seem completely voluntary, motor activity in both humans and rats is enslaved by an underlying intrinsic pattern that is similar across different time scales ranging from minutes to hours, independent of extrinsic scheduled events, environmental influences and activity levels (Hu et al., 2004; Hu et al., 2007; Hu et al., 2012). This phenomenon of self-similarity or fractality, in which temporal fluctuation patterns are repeated across different time scales, is known as scale invariance.

Researchers have sought intensively for anatomical structures responsible for this regulation. Lesions of the suprachiasmatic nucleus (SCN) in rodents abolish scale-invariant correlations of locomotor activity at scales larger than 4 h (Hu et al., 2007). This means that the hypothalamic clock orchestrating circadian (~24 h) rhythms in physiology and behavior (Welsh et al., 2010) also directs fluctuation patterns at time scales smaller than 24 h, either as a self-contained multi-oscillator system or by interacting with a network of other activity control nodes. Furthermore, compared to young people, older individuals show reductions in scale-invariant correlations for scales larger than 1.5 h, with an additional decrease in those with Alzheimer’s disease (Hu et al., 2009).
Both aging and Alzheimer’s disease are associated with disturbances of sleep and daily activity, which are thought to be caused by associated neuroanatomical changes in the SCN (Swaab et al., 1985; Zhou et al., 1995; Liu et al., 2000; Wu et al., 2006; Harper et al., 2008). Therefore, these results further support the role of the SCN in scale invariance also in humans (Pittman-Polletta et al., 2013) such that scale invariance of motor activity may potentially be used as a noninvasive marker of SCN function in humans (Hu et al., 2013).

However, previous observations of alterations in scale invariance were based on a relatively small sample size, with analyses limited to data during daytime, time scales smaller than 8 h, and subjects under extreme conditions such as Alzheimer’s disease and very old age (e.g., no or few healthy subjects between 30–50 years old). To better understand the effects of aging and SCN dysfunction on scale invariance, we assessed scale invariance of motor activity over a broader range of time scales from minutes up to 24 h, in much larger groups of healthy individuals (n = 72) and patients with a history of compression of the SCN (n = 90) – i.e., patients treated for large benign suprasellar tumors such as nonfunctioning pituitary macroadenomas (NFMA) and craniopharyngiomas. These tumors compress surrounding tissue and present with pituitary insufficiency, visual field defects and headache (Jaffe, 2006; Stamm et al., 2011). Following transsphenoidal adenomectomy, patients chronically suffer from daytime somnolence, reduced sleep efficiency, fragmented sleep-wake patterns, and alterations of diurnal melatonin and temperature rhythmicity (Ullrich et al., 2005; Biemrasz et al., 2011; Joustra et al., 2014a; Joustra et al., 2014b; Pickering et al., 2014; Pickering et al., 2017). These symptoms are strongly associated with suprasellar tumor extension (irrespective of hypopituitarism), implying damage to suprasellar structures, e.g., the optic tract or the ventral hypothalamus (most notably the adjacent SCN). The goal was to investigate the robustness of the scale invariance measure to detect healthy and possibly altered SCN function. We hypothesized that scale invariance is degraded in patients treated for suprasellar tumors and in a physiological condition of attenuated day–night rhythmicity, i.e., in older individuals.

Subjects and methods

Design

For this study, we analyzed wrist motor activity data collected from patients treated for NFMA or craniopharyngioma, and age-matched healthy individuals during normal daily activity at home. Using these data, detrended fluctuation analysis was performed to assess scale invariance. The Medical Ethics Committees of the Leiden University Medical Center and Copenhagen University Hospital approved the study protocols (P12.237 and H3.2011.057, respectively), and all subjects gave written informed consent.

Subjects

We examined wrist motor activity recordings of 72 healthy individuals (57 Dutch and 15 Danish; 34 women and 38 men; 20–70 years old) and 90 patients treated for NFMA or craniopharyngioma (75 Dutch and 15 Danish; 40 women and 35 men; 18–70 years old) that were collected from two previous studies (Joustra et al., 2014a; Joustra et al., 2014b; Pickering et al., 2014). Inclusion criteria for NFMA and craniopharyngioma were long-term remission (absence of, or stable residual adenoma) after transsphenoidal surgery for these adenomas at least one year ago, adequate and stable hormone replacement therapy for hypopituitarism (see below), and age between 18 and 70 years. Surgery was followed by radiotherapy in selected cases. We excluded patients with diagnosed sleep disorders (e.g., obstructive sleep apnea or periodic legs movement) or use of sleep-promoting- or psychotropic medication. The NFMA were staged according to the classification by Hardy–Wilson (Hardy, 1979). Visual field defects were diagnosed by standard Goldmann perimetry. An endocrinologist periodically evaluated the patients. Pituitary insufficiency (see Supplementary data for definitions) was treated with hydrocortisone, levothyroxine, recombinant human growth hormone (unless contraindicated or not preferred), testosterone in men and estrogen in combination with progestogens in premenopausal
women. Dosages were monitored and adjusted as required. Stable replacement was assumed when medication was not adjusted for 4 months, complaints were absent, and basal hormone levels showed adequate replacement.

The age-matched healthy participants fulfilled the same inclusion and exclusion criteria, except for pituitary pathology.

All Dutch subjects were evaluated at the Leiden University Medical Center in the Netherlands, mostly during the spring (68.6%) and winter (21.2%) of 2013. All Danish subjects were evaluated at the Rigshospitalet in Copenhagen Denmark, mostly in the fall (40.0%), winter (46.7%) and spring (13.3%) of 2011–2012.

**Actigraphy**

Motor activity levels were assessed continuously for 7 consecutive days and nights using an Actiwatch AW7 (CamNtech, Cambridge, UK) in Dutch subjects and an Actiwatch Spectrum (Philips Respironics, Murrysville, PA, USA) in Danish subjects, worn on the nondominant wrist. Subjects maintained their habitual sleep-wake schedules. The accelerometer records the highest amplitude of wrist movement per second in counts (one count representing 0.04 g), and sums these counts in epochs of 1 minute. Actigraphic measurements from Denmark were initially recorded in epochs of 30 seconds for 14 days. For the current analysis, only the first 7 days of the Danish data were used, and 1-minute epochs were formed by summation of two subsequent 30-second epochs.

Using nonparametric calculations, we calculated the interdaily stability, which quantifies similarity of rest-activity rhythms between days, and the intradaily variability, which indicates fragmentation of the day-night rhythm within individual days (Van Someren et al., 1999). Furthermore, averaging the activity patterns of the 7 registration days created an average 24-h activity pattern. From this 24-h pattern, the average movement per epoch of 1 minute was calculated for the hours spent awake, as determined by the actiwatch sleep analysis sleep scoring algorithm. To avoid any influence of differences in actigraphy sensitivity, analyses that include activity levels were only performed in Dutch subjects.

We refer to our previous work for the results of standard actigraphic variables as well as subjective sleep quality, fatigue and daytime sleepiness in these patients (Joustra et al., 2014a; Joustra et al., 2014b; Pickering et al., 2014).

**Assessment of scale invariance using detrended fluctuation analysis**

Detrended fluctuation analysis was used to determine correlations of activity fluctuations at time scales from minutes to 24 h. It derives the amplitude of activity fluctuations, \( F(n) \), at different time scales \( n \). To eliminate the potential effects of trends in the recordings, the second order polynomial function was used to detrend the data in the analysis. Scale invariance is characterized by a power-law form of the fluctuation function, \( F(n) = n^\alpha \), with the scaling exponent \( \alpha \) indicating correlations in fluctuations: \( \alpha = 0.5 \) represents no correlation in activity fluctuations, indicating complete randomness (or white noise) which is thought to reduce the system’s ability to orchestrate its subsystems appropriately in response to external stimuli; \( \alpha > 0.5 \) indicates positive correlations in activity fluctuations (i.e., large values have more probability of being followed by large values and vice versa); and \( \alpha = 1.5 \) indicates too much regularity (or Brownian/red noise), which restricts the functional responsiveness of the system, making it vulnerable to catastrophic events (Huikuri et al., 2000; Perkiomaki et al., 2001). Healthy physiological systems show a delicate balance between these two at \( \alpha \sim 1.0 \) (pink noise) (Goldberger et al., 2002) indicating strong positive correlations with the highest complexity. Detailed description of the method is described in Gu et al. (Gu et al., 2015). The scaling exponent \( \alpha \) was calculated using regression to obtain the best power-law fit of data: \( F(n) = n^\alpha \).

**Statistical analysis**

Statistical significance of mean differences between healthy participants and either of the patient groups were assessed using the two-tailed independent Student’s t-test or, in case the assumption of normality was not met (Shapiro–Wilk test), the
Mann–Whitney U test. Categorical data were compared using the Chi-square test or, when the expected cell count was ≤5, the Fisher’s exact test. Paired t-test was used to calculate statistical significance of differences between α1, α2 and α3. Three types of generalized linear regression models were used to assess determinants of outcome variables. To test the hypothesis that aging and disease are associated with degraded scale invariance, model 1 assessed the influence of age, gender, mean activity levels and disease (NFMA and craniopharyngioma combined) and their interactions on α1 (scaling exponent at time scales of 0.25–1.5 h), α2 (1.5–10 h) or α3 (10–24 h). To test the hypothesis that degraded scale invariance is associated with objective and subjective parameters of altered circadian rhythmicity, model 2 assessed the influences of both α2 and Δα1–α2 (as well as age, gender and activity levels) on actigraphic sleep duration, sleep efficiency, intradaily variability or interdaily stability (Joustra et al., 2014a), and subjective sleep quality (Pittsburgh sleep quality index (Buysse et al., 1989)), fatigue (multidimensional fatigue inventory (Smets et al., 1995)), or daytime sleepiness (Epworth sleepiness scale (Johns, 1991)). Lastly, to test the hypothesis that suprasellar extension causing visual field defects is associated with degraded scale invariance, model 3 assessed the effect of hypopituitarism, previous radiotherapy and preoperative visual field defects (as well as age, gender and activity levels) and their interactions on each α. In each model, the least-significant co-variates were removed sequentially, until all co-variates significantly contributed to the model. Then, Akaike’s information criterion, which measures the trade-off between goodness of fit and complexity of the model, was used to determine whether the model could be further simplified. The regression coefficient B was used to express effect size. Differences were considered statistically significant at p < 0.05.

**Results**

**Clinical characteristics**

The 72 healthy subjects had a median age of 55.5 years (range 21.0–70.6 years) and 47.2% were women.

Patients with NFMA (n = 68, 48.5% women) in long-term remission after transsphenoidal surgery for suprasellar tumor extension had a median age of 59.4 years (range 26.0–70.1 years) (Table 1). Before surgery, suprasellar tumor extension was observed in 94% of cases, and visual field defects in 77.9%. At the time of the actigraphic evaluation, hypopituitarism was present in 82.4%, and all patients received proper and stable replacement therapy except for optional growth hormone replacement, which was left untreated in 15 of 49 growth hormone deficient patients. NFMA patients displayed more intradaily variability (p = 0.005) and less interdaily stability (p = 0.026) than the healthy group.

Data represent median (interquartile range) or number (percentage). aHardy–Wilson classification (Hardy, 1979) minimal II-B. bAverage activity per minute during hours spend awake in counts, each count representing 0.04 g of wrist acceleration per second. NFMA: nonfunctioning pituitary macroadenoma. VFD: visual field defects. *p < 0.05 or **p < 0.01 compared to healthy subjects.
Furthermore, 22 patients in long-term remission after surgery for craniopharyngioma (31.8% women), with a median age of 51.7 years (range 18.2–70.2 years) were studied. The majority of the patients had visual field defects preoperatively (63.6%). At the time of the actigraphic evaluation, all had hypopituitarism, vasopressin deficiency was present in 63.6%, and all received proper and stable replacement therapy. Differences between craniopharyngioma patients (CP) and the healthy group in intradaily variability and interdaily stability did not reach statistical significance ($p = 0.109$ and $p = 0.058$, respectively). CP displayed a higher body mass index than healthy participants ($p = 0.027$). Dutch and Danish participants, both patients and healthy subjects, did not differ significantly in gender or age.

Scale invariance of activity fluctuations

Figure 1A shows the averaged detrended fluctuation function $F(n)$ across time scales 0.25–24 h for each group. As can be observed, scaling behavior differed in three regions: $n_1 \approx 0.25–1.5$ h, $n_2 \approx 1.5–10$ h and $n_3 \approx 10–24$ h. These breakpoints can be seen more clearly in Figure 1B, representing the change in $F(n)$ per $n [F(n)/n]$ with slope $\alpha'$ (which is $\alpha - 1$). Slopes $\alpha_1$, $\alpha_2$ and $\alpha_3$ were calculated for the three regions $n_1$, $n_2$ and $n_3$, respectively (Figure 2). Complex activity fluctuations with strong correlations ($\alpha_1 \approx 1$) were observed across the lower time scales ($\alpha_1$ at $n_1 < 1.5$ h) in healthy subjects ($\alpha_1: [\text{mean} \pm \text{SD}]: 0.98 \pm 0.07$), NFMA ($\alpha_1: 0.99 \pm 0.07$) and craniopharyngioma ($\alpha_1: 0.99 \pm 0.06$). For scales from 1.5 to 10 h ($n_2$), all groups showed a reduction in scale-invariant correlations, as the scaling exponent $\alpha_2$ decreased significantly (all $p < 0.001$) in healthy subjects ($\alpha_2: 0.89 \pm 0.09$), NFMA ($\alpha_2: 0.85 \pm 0.09$) and craniopharyngioma patients ($\alpha_2: 0.86 \pm 0.09$). For the time scales from 10 to 24 h ($n_3$), a dramatic inversion of scale-invariant correlations (all $p < 0.001$) toward red noise (also known as Brownian noise) was observed in healthy subjects ($\alpha_3: 1.27 \pm 0.21$), NFMA ($\alpha_3: 1.26 \pm 0.17$) and craniopharyngioma ($\alpha_3: 1.20 \pm 0.19$).

There were no significant effects of activity levels, age, gender or disease on $\alpha_1$ (model 1). For the second timescale region $n_2$, $\alpha_2$ was lower (more random activity fluctuations) in patients as compared to controls ($p = 0.014$) (Table 2). Disease and gender showed two interaction effects on $\alpha_2$ ($p = 0.010$): women showed lower $\alpha_i$ than men only within healthy subjects, and the decrease in $\alpha_2$ in patients was significantly stronger in men (Figure 3). Within the healthy control group, one-way ANOVA showed a difference in $\alpha_2$ between the age groups ($p = 0.003$), i.e., $\alpha_2$ was around 1.0 (indicating the most complex fluctuations) in the youngest subgroup (18–33 years) and was significantly smaller in the other age subgroups (Tukey post hoc). The age groups were based on those used in the study of Hu et al. (Hu et al., 2009), and no effects of age groups were observed in patients ($p = 0.595$). We also observed a small interaction effect of age and activity levels on $\alpha_3$ ($p = 0.021$), as the positive association between activity and $\alpha_2$ was stronger in older subjects. The difference between $\alpha_1$ and $\alpha_2$ ($\Delta = \alpha_1 - \alpha_2$), as a direct test of a decrease in scale invariance, was solely influenced by disease ($p = 0.006$). For the largest time-scale region $n_3$, a larger $\alpha_3$ correlated with age ($p = 0.003$, $+0.193$ per decade), and with higher activity level ($p = 0.001$, $+0.472$ for every increase of 100 activity counts per minute). In addition, the association between $\alpha_3$ and activity levels was influenced by age, i.e., it was positive in subjects <66 years old and negative at > 66 years old (Supplemental Figure S2). Although statistically significant, this interaction effect was considerably smaller than the individual effects of age and activity ($p = 0.004$, $B = -0.069$).

Furthermore, lower $\alpha_2$ was associated with more fatigue ($p = 0.017$) and larger $\Delta = \alpha_1 - \alpha_2$ with better intradaily stability ($p = 0.032$) (model 2). Neither $\alpha_2$ nor $\Delta = \alpha_1 - \alpha_2$ were associated with subjective sleep quality, daytime sleepiness, sleep duration, sleep efficiency or intradaily variability.

Lastly, within patients, we observed a significant interaction between the effects of activity levels and radiotherapy on $\alpha_2$ (model 3), as the association between higher activity levels and higher $\alpha_2$ was only present in patients without radiotherapy ($p = 0.014$, $B = -0.067$, Supplemental Figure S1). No effects of patient characteristics (model 3) on $\alpha_1$, $\alpha_1 - \alpha_2$ or $\alpha_3$ were observed.
The results of this study demonstrate that scale invariance of activity patterns in humans degrades already during midlife. Larger attenuations of scale invariance were observed in patients treated for suprasellar tumors, as well as in women, with older age, and with lower activity levels.

Within the entire time scale window from minutes to 24 h, complex scale-invariant correlations were only observed for time scales smaller than 1.5 h, and became more random at time scales 1.5–10 h. Hu et al. observed a remarkably similar breakpoint at 1.5 h in older individuals (80.8 ± 8.6 years old) and in very old patients with Alzheimer’s disease (Hu et al., 2009). The

**Discussion**

The results of this study demonstrate that scale invariance of activity patterns in humans degrades already during midlife. Larger attenuations of scale invariance were observed in patients treated for suprasellar tumors, as well as in women, with older age, and with lower activity levels.

**Figure 1.** Average detrended fluctuation functions F(n) from locomotor activity data of 72 healthy controls, 68 NFMA patients and 22 craniopharyngioma patients. Data are shown on log-log plots and curves are vertically shifted in [A] for better visualization of differences between groups (vertical offset does not alter the slope). The scaling behavior can be separated in three time scale regions based on two breakpoints at ~1.5 h and ~10 h. The break points can be seen more clearly when F(n) is divided by time scale n in [B], indicating the change in F(n) per time unit n. The straight lines represent perfect scale-invariance α = 1.00 [A] or α’ = 0.00 [B].
attenuation of scale-invariant correlations for scales 1.5–10 h in those groups were larger than we observed in our patients and healthy subjects, which may be explained by more severe SCN dysfunction in old age and Alzheimer’s disease (Swaab et al., 1985; Zhou et al., 1995; Liu et al., 2000; Wu et al., 2006; Harper et al., 2008). The study reported no breakpoint in scale invariance in healthy young subjects (n = 13, 25.5 ± 6.1 years) (Hu et al., 2009), which was confirmed in our study as Figure 3 shows an α₂ around 1.0 in the corresponding healthy young age group (18–33 years). In addition, our results show that α₂ decreases quickly after the age of 33 year, especially in women.

Our observation of a second breakpoint at ~10 h has not been reported previously, either because large time scales were not assessed (Hu et al., 2009) or because the exponent α was only calculated for the entire observation window (Hu et al., 2007), although the two breakpoints were visible in their display of data (Hu et al., 2007). As we observed no effect of disease on activity correlations at time scales larger than 10 h, the increased regularity in this time scale region may depend less on SCN functioning and more on environmental and behavioral cues, (e.g., our environmental light-dark cycle, sleep-wake...
schedule and daily work schedule). Therefore, although complexity (alpha close to one) is a biomarker of healthy physiology, this might not be the case, or the intrinsic patterns can be masked, at larger time scales where imposed environmental rhythms play an important role.

Aging was associated with further increased regularity at this larger time scale, which might imply reduced integration and orchestration of the SCN with other oscillators of motor activity control, or might reflect more dominating environmental or behavioral influences.

We observed an additional decrease of $\alpha_2$ in patients treated for tumors with suprasellar extension. Furthermore, Figure 3 shows that complex scale-invariant correlations during time scales 1.5–10 h are already decreased in young patients as compared to healthy controls. A history of suprasellar tumor extension is therefore an additional risk factor for a decrease in the scale-invariant correlations at time scales that have previously been shown to be affected by the SCN. Within patients, we observed an association between higher activity levels and larger $\alpha_2$ (close to 1) only in those that without a history of radiotherapy, but there was no main effect of radiotherapy on $\alpha_2$. The explanation for this phenomenon remains unclear, but due to the observational nature of the data we cannot exclude confounding factors, e.g., by indications for radiotherapy.

Although Gu et al. observed strong effects of regular exercise on scale invariance in mice (Gu et al., 2015), we observed marginal associations of $\alpha_2$ with differences in activity level. As our study is observational, we cannot draw causal conclusions, and variations in activity might have been too small to show an effect. Future intervention studies in cohorts of young versus middle-aged healthy individuals should be performed to determine whether significantly improving activity levels results in a change in scale-invariant correlations.

The observed attenuation of scale-invariant correlations at time scales between 1.5–10 h in our healthy subjects indicated that even in healthy middle-aged individuals, the physiological balance between regularity and randomness is suboptimal. The complex physiological fluctuations that resemble pink noise are thought to reflect system plasticity and adaptability in response to unpredictable stimuli and stressors because the alterations have been associated with pathologic conditions. For instance, altered correlations in heart rate fluctuations are observed in patients with heart failure (Huikuri et al., 2000; Makikallio et al., 2001a; Makikallio et al.,
and atrial fibrillation (Vikman et al., 1999), and more random gait is observed in Huntington’s disease (Hausdorff et al., 1997). The clinical significance of suboptimal scale invariance in activity patterns has not been established yet, although lower activity correlation at 1.5–10 h or its difference from the correlation at smaller time scales has been associated with increased age, with Alzheimer’s disease and with neurotransmitter content in the SCN in postmortem studies (Hu et al., 2009; Hu et al., 2013). In the current study, decreased $\alpha_2$ was associated with complaints of fatigue. Future studies are warranted to investigate the mechanism underlying the association.

Strengths of the current study were the large groups included in the study, allowing investigation of various associations. Limitations include the sensitivity of the actigraph, whose signal-to-noise ratio becomes more unfavorable during periods of low upper extremity movements, especially during the sleep/nap episodes. We did not consider the potential effects of light intensity on activity patterns. The sample size in our younger subgroups was small, requiring further studies to determine the exact time course of deterioration of $\alpha_2$ across age. Also, the extent of SCN dysfunction in our patients was not known as no direct measure of SCN functioning exists. However, patients had other indirect signs of SCN dysfunction, i.e., altered objective and subjective sleep-wake cycle (Biermasz et al., 2011; Joustra et al., 2014a; Pickering et al., 2014). In a subset of patients, rhythmicity of melatonin, temperature and sleep quality were measured and found to be disturbed, albeit in variable patterns (Joustra et al., 2014b).

In conclusion, the results of this study have demonstrated that healthy middle-aged subjects show robust scale invariance of activity patterns at time scales of up to 1.5 h, which attenuated at larger scales leading to more random activity fluctuations at time scales from 1.5 to 10 h and more regular activity patterns at time scales from 10 to 24 h. Activity patterns at time scales between 1.5 and 10 h were more affected in patients with suprasellar tumors, in line with previous reports associating these time scales with SCN function. We also observed effects of gender on activity patterns at time scales 1.5–10 h, as well as a rapid decline in activity correlations with age (starting as early as approximately 33 years old). Scale invariance is therefore already starting to become fragile in healthy middle-aged subjects.
