Bohr^{1,6}, Niels de Wind³, Linda Hildegard Bergersen^{2,4} & Lene Juel Rasmussen¹

Nucleic acids, which constitute the genetic material of all organisms, are continuously exposed to endogenous and exogenous damaging agents, representing a significant challenge to genome stability and genome integrity over the life of a cell or organism. Unrepaired DNA lesions, such as single- and double-stranded DNA breaks (SSBs and DSBs), and single-stranded gaps can block progression of the DNA replication fork, causing replicative stress and/or cell cycle arrest. However, translesion synthesis (TLS) DNA polymerases, such as Rev1, have the ability to bypass some DNA lesions, which can circumvent the process leading to replication fork arrest and minimize replicative stress. Here, we show that Rev1-deficiency in mouse embryo fibroblasts or mouse liver tissue is associated with replicative stress and mitochondrial dysfunction. In addition, Rev1-deficiency is associated with high poly(ADP) ribose polymerase 1 (PARP1) activity, low endogenous NAD⁺, low expression of SIRT1 and PGC1 α and low adenosine monophosphate (AMP)-activated kinase (AMPK) activity. We conclude that replication stress via Rev1-deficiency contributes to metabolic stress caused by compromised mitochondrial function via the PARP-NAD⁺-SIRT1-PGC1 α axis.

DNA is continuously challenged by endogenous DNA damaging agents, including reactive oxygen species (ROS) and reactive aldehydes, that are present in normal cells under normal physiological conditions. It has been estimated that more than 10,000 oxidative DNA lesions arise spontaneously per mammalian cell per day^{1,2}. Many types of endogenous DNA damage are quickly removed by base excision repair (BER), nucleotide excision repair (NER), mismatch repair (MMR) or double strand break repair (DSBR)³ pathways. However, DNA lesions that persist due to inefficient repair can be mutagenic, and/or can inhibit DNA replication/transcription, trigger apoptosis, cell cycle arrest or cellular senescence, or activate the DNA damage response (DDR) pathway⁴. Recent studies demonstrate that constitutive DDR consumes a large amount of energy in the form of adenosine triphosphate (ATP) and/or nicotinamide adenine dinucleotide (NAD⁺), such that chronic replicative stress is frequently associated with metabolic stress caused by energy imbalance or poor energy homeostasis⁵⁻⁷. Constitutive activation of DDR also creates a vicious cycle, as it can increase the abundance of ROS, which in turn generates more oxidative DNA lesions⁸. A key enzyme in DDR is poly(ADP) ribose polymerase 1 (PARP1), whose high consumption of intracellular NAD⁺ can contribute to depletion of this important metabolite and lead to mitochondrial dysfunction⁹⁻¹¹.

When a cell's capacity to repair DNA lesions is exceeded, persistent DNA lesions arise, some of which block the progression of DNA replication forks. Typically, a cell responds by activating additional origins of replication, or by activating translesion synthesis (TLS)⁴ DNA polymerases, such as Rev1. Rev1 belongs to the Y-family of DNA polymerases, enzymes that carry out post-replication gap-filling DNA synthesis using a lesion-containing DNA strand as a template for the TLS reaction^{12,13}. Rev1 also recruits other TLS polymerases to sites of DNA

damage^{14–16}. TLS gene mutations and sequence variants are involved in many human neurological disorders as well as cancer^{17–20}.

In *Saccharomyces cerevisiae*, The first 148 amino acids of Rev1 are sufficient to direct the localization of GFP to the mitochondria of yeast and Rev1 is thought to play a role in mutagenesis in that organelle²¹. In Rev1-deficient mouse embryo fibroblasts (*Rev1*^{-/-} MEFs), ssDNA gaps accumulate during DNA replication¹³ and over time, proliferating tissues and stem cells are depleted in *Rev1*^{-/-} mice relative to wild type (WT) controls²². *Rev1*^{-/-} mice also have a growth defect^{13,23}. To date, defects in Rev1 have not been linked to mitochondrial dysfunction in mammalian cells.

This study provides evidence that Rev1 is required for normal mitochondrial function and energy homeostasis in mouse cells. Furthermore, data presented here suggest that *Rev1*^{-/-} MEFs express increased levels of constitutively activated PARP1, reduced levels of endogenous NAD⁺, reduced expression of SIRT1 and PGC1 α , reduced adenosine monophosphate (AMP)-activated kinase (AMPK) activity, and reduced autophagy and mitophagy. We conclude that replication stress caused by Rev1-deficiency contributes to cellular and organismal metabolic stress via mitochondrial dysfunction involving the PARP-NAD⁺-SIRT1-PGC1 α axis⁷.

Results

In *S. cerevisiae* Rev1 localizes to the mitochondria, where it is thought to participate in replication and mutagenesis of the mitochondrial genome (mtDNA)^{21,24,25}. Our past studies also suggest that *S. cerevisiae* Rev1, as well as Rev3, and Rev7, plays a role in mitochondrial-mediated mutagenesis²⁶. The goal of the present study was to explore if Rev1 plays a role in mitochondrial function in mammalian cells.

Mitochondrial function is impaired in *Rev1*^{-/-} cells. While the subcellular localization of murine Rev1 has not been determined, several reports indicate that human Rev1 is predominantly a nuclear protein^{27,28}. Results presented in Fig. 1a suggest that murine Rev1 localizes predominantly to the nucleus. However, it might still affect mitochondrial functions.

Mitochondrial parameters were measured in primary liver cells from 5 month old WT and *Rev1*^{-/-} mice (Figure S1) and in WT and *Rev1*^{-/-} MEFs (Figs. 1c–e). Standard measures of electron transport chain (ETC) activity and oxidative phosphorylation (OXPHOS) were performed in an extracellular flux analyzer (Seahorse); these parameters were similar in WT and *Rev1*^{-/-} liver tissue (Figures S1a, S1b); however, citrate synthase (CS) activity was lower in *Rev1*^{-/-} liver tissue compared to WT (Fig. 1b). In contrast the basal respiration rate was approximately 30% higher in *Rev1*^{-/-} MEFs than in WT MEFs (Fig. 1c). In MEFs treated with oligomycin to inhibit ATP synthase (complex V), respiration was 52% of basal respiration in WT and 46% of basal respiration in *Rev1*^{-/-} cells (Fig. 1d). One interpretation is that ATP production is increased in *Rev1*^{-/-} MEFs compared to WT MEFs²⁹. The results also showed that reserve capacity was approximately 25% lower in *Rev1*^{-/-} MEFs than in WT MEFs (Fig. 1e). This suggests that loss of Rev1 may impair mitochondrial functions²⁹. A constant increase in mitochondrial activity associates with increased mitochondrial membrane potential (MMP) and ROS production⁸. Membrane potential and ROS were elevated in *Rev1*^{-/-} MEFs (Fig. 1f,g, S6), although the level of ROS increased gradually over 3 weeks in culture. The latter increase was not observed in WT MEFs (Fig. 1g).

Cellular stress and increased demand for ATP can lead to increases in respiration and MMP^{30,31}. To assess this, ATP abundance was measured in WT and *Rev1*^{-/-} MEFs (Fig. 1h). The results showed that total ATP was approximately 2-fold lower in *Rev1*^{-/-} MEFs than in WT MEFs. This could reflect either decreased synthesis and/or increased consumption of ATP.

The expression of SOD2 is decreased in *Rev1*^{-/-} MEFs. Superoxide dismutase 2 (SOD2) is a mitochondrial matrix protein that converts highly reactive superoxide (O₂^{•-}) to less reactive hydrogen peroxide (H₂O₂), thereby protecting proteins, lipids, and DNA from oxidative damage^{8,32,33}. Interestingly, SOD2 protein expression was decreased in *Rev1*^{-/-} MEFs compared to WT MEFs (Fig. 1i). This could contribute to the increased abundance of ROS in the mitochondria of *Rev1*^{-/-} cells^{8,34}. Decreased SOD2 would also be expected to increase sensitivity of *Rev1*^{-/-} cells to oxidative stress. Menadione is a quinone, which is metabolized and reduced to semi-quinone by flavoprotein within the mitochondrial inner membrane. In the presence of molecular oxygen, it enters the redox cycle to generate ROS such as superoxide anion radicals, H₂O₂, and Hydroxyl radical, which can induce oxidative stress in cells (Figure S2)^{34,35}. Consistent with this prediction, *Rev1*^{-/-} MEFs were more sensitive to menadione (5 to 20 μ M) than WT MEFs (Fig. 1j), as measured by survival in a colony formation assay. The results also show that lower concentrations of menadione increase survival in WT MEFs, but not in *Rev1*-deficient MEFs (Fig. 1j).

Mitochondrial OXPHOS proteins are more abundant in *Rev1*-deficient cells. We investigated the mitochondrial content by analyzing the abundance of selected OXPHOS subunits and mtDNA content in WT and *Rev1*^{-/-} liver tissue and MEFs. The results showed that complex I, II and III proteins are more abundant and mtDNA content is higher in *Rev1*^{-/-} MEFs than in WT MEFs (Fig. 2a–c). In liver cells from female mice, complex II (SDHB) and complex IV (COXIV) were significantly higher in *Rev1*^{-/-} than in WT (Figure S3a), with a general trend towards increased expression of all respiratory complexes in liver from *Rev1*-deficient mice. However, some data on liver tissue from male mice were not statistically significant (Figs 2f,g, S3a,b). The increase in mtDNA content in the liver of *Rev1*^{-/-} mice is also not statistically significant (P = 0.089) (Figs 2h, S3c). In addition, expression of PGC1 α was significantly lower in *Rev1*^{-/-} MEFs than in WT MEFs (Fig. 2d,e), but significantly higher in liver cells from female *Rev1*^{-/-} mice (Figures S3d and S5). Increased mitochondrial content was shown to be associated with a decrease in PGC1 α and mitophagy³⁶. We, therefore, tentatively conclude that the mitochondrial biogenesis is lower in *Rev1*-deficient MEFs, but higher in the liver of 5 months old *Rev1*^{-/-} mice (Figs 2f,i, S3d).

Figure 1. Mitochondrial function is impaired in *Rev1*^{-/-} Cells. **(a)** Fluorescent microscopy analysis of subcellular localization of Rev1 protein. *Rev1*^{-/-} MEFs transfected with plasmid containing Rev1-YFP fusion protein. MitoTracker Red and DAPI were used to visualize mitochondria and nucleus respectively (Size bar: 5 μM). **(b)** CS activity in the liver of 5 months old WT and *Rev1*^{-/-} mice. **(c–e)** Basal and ATP linked respiration and reserve capacity in WT and *Rev1*^{-/-} MEF cells (n = 5). Basal respiration was calculated and normalized to the protein content (t = 4.808; df = 4). ATP linked respiration and reserve capacity were measured upon the injection of oligomycin (0.3 μM) and FCCP (1.5 μM) respectively. ATP linked respiration (t = 3.875; df = 4) and reserve capacity (t = 11.68; df = 4) are represented as relative decrease and increase in OCR, respectively, compared to basal respiration. **(f,g)** Flow cytometry analysis of MMP and mitochondrial ROS in WT and *Rev1*^{-/-} MEF cells. The MMP was measured 3 weeks after initiation of cell culture (n = 4; t = 3.29; df = 3). The mitochondrial ROS was measured after 10 days and again after 3 weeks (n = 3; t = 9.777; df = 2). **(h)** The relative ATP level in WT and *Rev1*^{-/-} MEFs after 3 weeks (n = 3; t = 11.7; df = 2). **(i)** Expression of SOD2 (mnSOD) in WT and *Rev1*^{-/-} MEFs (n = 3). **(j)** Colony forming assay, cells treated with increasing concentrations of menadione. Colonies were stained with crystal violet and counted after one week of growth. n = sample number; t = t value; df = degree of freedom; *p < 0.05. **p < 0.01. ***p < 0.001. ****p < 0.0001. Data presented are mean ± M.S.E. Dark bars: WT and gray bars: *Rev1*^{-/-}.

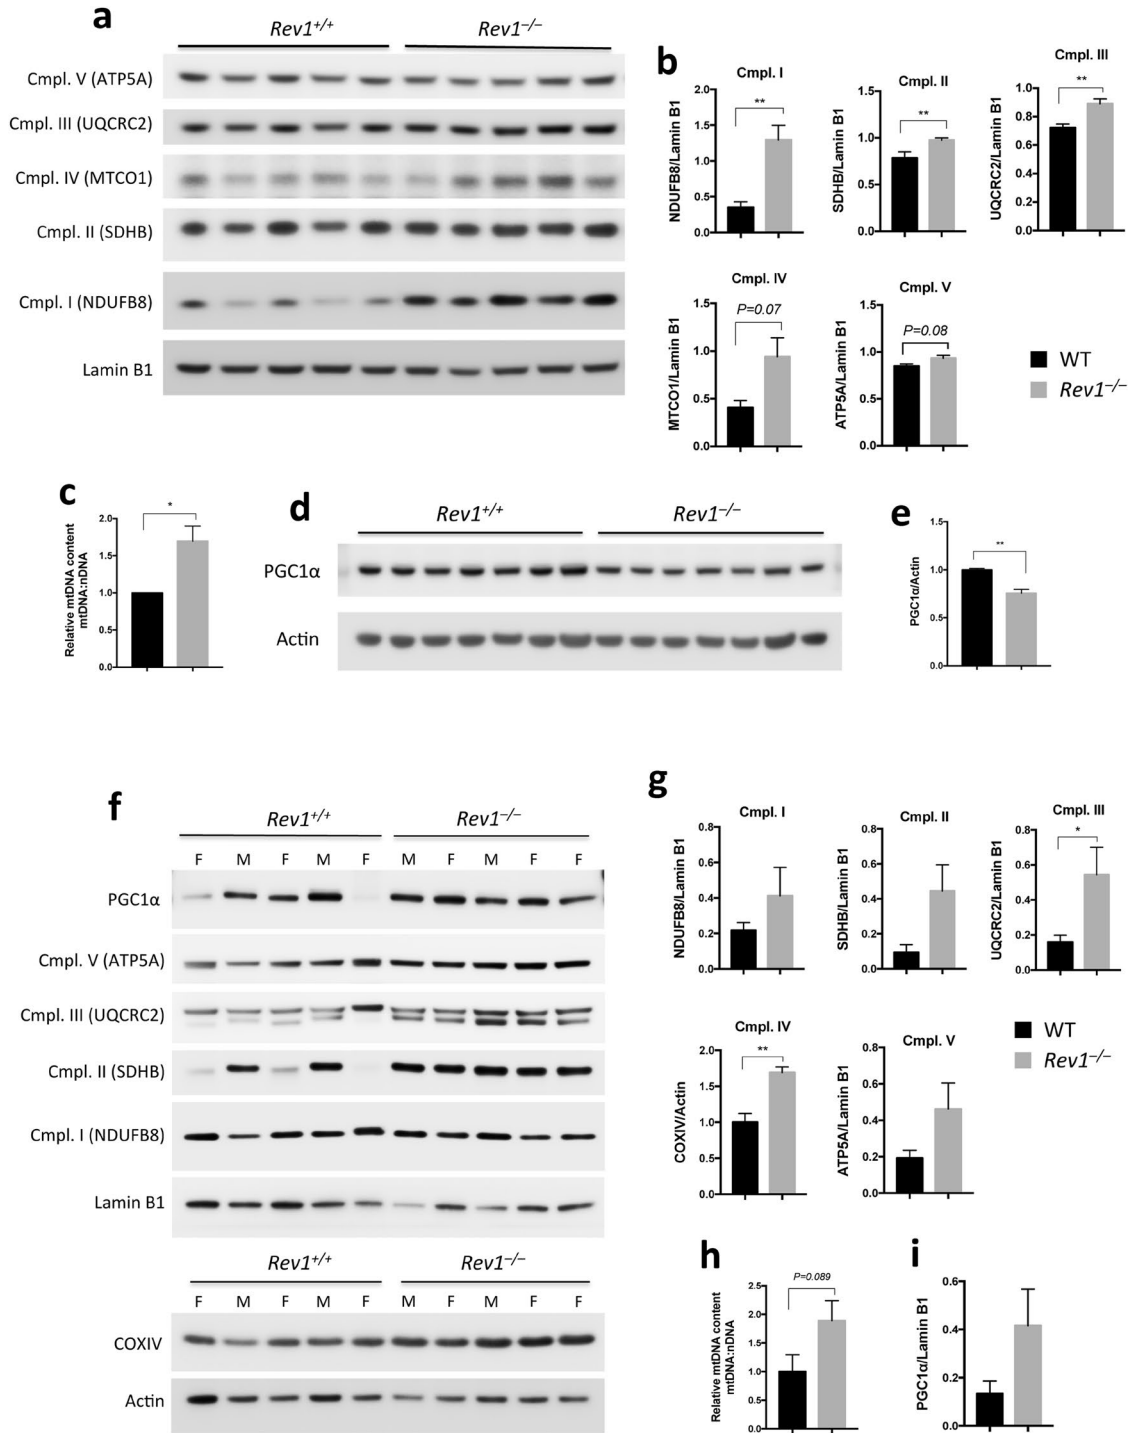

Figure 2. Mitochondrial content and biogenesis. **(a,b,f,g)** Immunoblot analysis of the subunits of mitochondrial complexes in MEF cells (n = 5; df = 4) **(a,b)** and in liver (n = 5; df = 8) **(f,g)**. **(b,g)** Quantifications of Cmpl. I–V protein levels from **(A)** MEFs and **(f)** liver, respectively. Cmpl. I (NDUFB8, NADH dehydrogenase 1 beta subcomplex subunit 8) (MEFs: t = 4.981; Liver: t = 1.17); Cmpl. II: SDHB (Succinate dehydrogenase iron-sulfur subunit) (MEFs: t = 3.685; Liver: t = 2.23); Cmpl. III: UQCRC2 (Cytochrome b-c1 complex subunit 2) (MEFs: t = 5.411; Liver: 2.383); Cmpl. IV: MTCO1 (Cytochrome c oxidase subunit 1) (MEFs: t = 2.378); COXIV (Cytochrome c oxidase subunit 4) (Liver: t = 4.79); Cmpl. V: ATP5A (ATP synthase subunit alpha) (MEFs: t = 2.302; Liver: t = 1.806). **(c,h)** Analysis of mtDNA content number by qPCR in MEF cells (n = 4; t = 3.544; df = 3) **(c)** and liver (n = 5; t = 1.944; df = 8) **(h)**. The mtDNA content was calculated as the mtDNA/nDNA ratio using primers specific for the mitochondrial TrnL1 and nuclear β -2-microglobulin (β 2M) genes. **(d)** Immunoblot analysis of PGC1 α in MEFs (n = 7; t = 5.764; df = 6). **(e)** Quantification of PGC1 α protein levels from **(d)** MEFs. **(i)** Quantification of PGC1 α protein level in the liver of WT and *Rev1*^{-/-} 5 months old mice (t = 1.761). n = sample number; t = t value; df = degree of freedom; *p < 0.05. **p < 0.01. ***p < 0.001. ****p < 0.0001. Data presented are mean \pm M.S.E.

Figure 3. Analysis of mitochondrial morphology in MEF cells and liver hepatocytes. The TEM images of mitochondrial morphology in WT and *Rev1*^{-/-} MEF cells after 8 passages (a) and hepatocytes of 5 months old mice (b). Size bars: 2 μM.

Altered mitochondrial morphology and decreased mitophagy in *Rev1*^{-/-} cells. Change in mitochondrial morphology may reflect altered mitochondrial bioenergetics and/or increased energy demand³⁷. Here, we compared mitochondrial morphology in WT and *Rev1*^{-/-} MEFs and hepatocytes using Transmission Electron Microscopy (TEM) (Fig. 3a,b). We observed fragmented and elongated mitochondria in *Rev1*^{-/-} hepatocytes and MEFs at a much greater frequency than in WT cells, where mitochondria were more homogenous in size and shape. One explanation might be that surveillance and maintenance of the mitochondrial pool is less efficient in *Rev1*-deficient cells; another possibility is that the rates of mitochondrial fission/fusion and/or mitophagy/autophagy are altered in *Rev1*^{-/-} cells^{30,38–40}.

Autophagy is an intracellular process by which dysfunctional cellular components are degraded via the action of lysosomes. The rate of autophagy increases in response to starvation, growth factor deprivation, endoplasmic reticulum (ER) stress, infection, and other forms of stress⁴¹. Microtubule-associated protein 1 A/1B-light chain 3 (LC3)-related proteins are markers of autophagy, because of their critical roles in this pathway⁴¹. Cells initially synthesize the unprocessed polypeptide LC3-I, which is converted to LC3-II during the final stage of autophagy. Therefore, the rate at which LC3-I is converted to LC3-II reflects the rate of autophagy⁴². Here, we observed that the deduced rate of autophagy was similar in liver cells from WT and *Rev1*^{-/-} female mice (Fig. 4a,b), but appeared to be higher in liver cells from *Rev1*^{-/-} male mice than in control cells (Fig. 4a,b). Autophagy and mitophagy was also measured in MEFs after exposure to rotenone (2 or 4 μM) (Fig. 4e,f). Rotenone is a mitochondrial toxin, which inhibits complex I activity and induces mitochondrial specific autophagy (mitophagy)³⁶. There

Figure 4. Analysis of autophagy and mitochondrial dynamics in MEFs and hepatocytes in WT and *Rev1*^{-/-} cells. **(a)** Analysis of autophagy by immunoblot and **(b)** quantification of LC3B-II/Actin ratio in the liver of WT and *Rev1*^{-/-} 5 months old mice (females, n = 3; males n = 2). **(c)** Immunoblot analysis of total and phosphorylated DRP1 (Ser616) in the liver of WT and *Rev1*^{-/-} 5 months old mice (male and females together, n = 5). **(d)** Quantification of total and phosphorylated DRP1 (Ser616) from panel (c). **(e)** Immunoblot with WT and *Rev1*^{-/-} MEF cells, treated with rotenone (0 μ M, 2 μ M and 4 μ M) for 12 hrs (n = 3; df = 2). **(f)** The LC3B-II/Actin ratio in untreated and treated MEF cells after 12 hrs (0 μ M: t = 1, 2 μ M: t = 2.2, 4 μ M: t = 14). **(g,h)** Analysis of total DRP1 (0 μ M: t = 0.56; 2 μ M: t = 5.1; 4 μ M: t = 7.36) and phosphorylated DRP1 (Ser616) (0 μ M: t = 3.96; 2 μ M: t = 21.93; 4 μ M: t = 14.14) in untreated and treated MEFs. **(i,j)** Analysis of total AMPK α (0 μ M: t = 2.09; 2 μ M: t = 0.56; 4 μ M: 81.52) and phospho- AMPK α (Thr172) (0 μ M: t = 64.37; 2 μ M: t = 21.2; 4 μ M: t = 4.67) in untreated and treated MEFs. n = sample number; t = t value; df = degree of freedom; *p < 0.05. **p < 0.01. ***p < 0.001. ****p < 0.0001. Data presented are mean \pm M.S.E. Dark bars: WT and gray bars: *Rev1*^{-/-}.

were no significant differences in autophagy flux between untreated WT and *Rev1*^{-/-} MEFs. Untreated *Rev1*^{-/-} cells showed a slight increase in autophagy (Fig. 4f). In response to treatment with rotenone, the expression and conversion of LC3B-I to LC3B-II was decreased in *Rev1*^{-/-} cells, while it was increased in WT cells (Fig. 4e,f). To confirm this decrease in mitophagy in *Rev1*^{-/-} MEF cells, we assessed the intensity of mitophagy specific dye using confocal microscopy in live cells after treatment with rotenone (see methods for details) and observed that the intensity of mitophagy marker is significantly higher ($P < 0.0001$) in WT cells compared to *Rev1*^{-/-} MEFs (Figure S7). This suggests that stress-induced mitophagy may be impaired in *Rev1*-deficient cells.

The rate of mitochondrial fission was also examined in WT and *Rev1*-deficient cells⁴³. Fission is a process through which mitochondria divide and give rise to smaller mitochondria. DRP1 is a GTPase member of the dynamin family, that oligomerizes on the surface of the outer mitochondrial membrane and promotes mitochondrial fission^{44,45}. DRP1 is regulated via phosphorylation at Ser616 by cyclin dependent kinase (CDK1)/Cyclin B, which stimulates DRP1 activity and promotes efficient distribution of mitochondria to daughter cells during mitosis⁴⁶. We measured total and Ser616-phosphorylated DRP1 (pDRP1 Ser616) (Fig. 4c–e) and observed a higher level of total DRP1 but a lower level of p-DRP1 Ser616 in the liver cells from *Rev1*^{-/-} mice (Fig. 4c,d). This result is consistent with suppressed DRP1 activity, less frequent mitochondrial fission and the presence of elongated mitochondria in *Rev1*-deficient cells. In contrast, DRP1 expression was similar in WT and *Rev1*^{-/-} MEFs. However, in response to treatment with rotenone, the total DRP1 protein is decreased in *Rev1*^{-/-} MEFs while it increased in WT (Fig. 4e,g). p-DRP1 Ser616 was higher in untreated *Rev1*^{-/-} than in untreated WT MEFs. The level of pDRP1 Ser616 increased significantly in rotenone treated WT and *Rev1*^{-/-} MEFs and these changes were greater in treated *Rev1*^{-/-} MEFs than in WT. We tentatively conclude that among the multiple factors that regulate mitochondrial dynamics and autophagy in MEFs, several are influenced by *Rev1* genotype^{47,48}.

Phosphorylation of AMPK α is decreased in *Rev1*^{-/-} cells. AMPK positively regulates autophagy through its ability to inhibit mechanistic target of rapamycin (mTOR), a negative regulator of autophagy. However, AMPK also phosphorylates ULK1 and Raptor, which promotes autophagy^{47,49–51}. Active DRP1 binds to the mitochondrial fission receptor (MFF) and phosphorylation of MFF by AMPK is required for the oligomerization of DRP1 on the mitochondrial outer membrane⁵¹. In addition, AMPK is sensitive to the AMP:ATP ratio, and is considered to be a “metabolic sensor.” When the AMP:ATP ratio increases, the AMPK catalytic subunit, AMPK α is phosphorylated by LKB1 on Thr172, which stimulates its kinase activity. Activated AMPK phosphorylates downstream targets to decrease ATP consumption and promote mitochondrial biogenesis and ATP production⁴⁷.

Here, we observed that while expression of AMPK α was higher the abundance of pAMPK α Thr172 was significantly lower in *Rev1*^{-/-} cells (Fig. 4e,i,j). 5-Aminoimidazole-4-carboxamide ribonucleotide (AICAR) is an analog of adenosine monophosphate (AMP) that stimulates AMPK activity. Therefore, WT and *Rev1*-deficient cells were treated with AICAR, and the effect on mitochondrial bioenergetics was investigated (Figure S4). The results show no significant change in basal- or ATP-linked respiration in *Rev1*^{-/-} or WT MEFs treated with AICAR relative to untreated controls. However, reserve capacity increased significantly in WT MEFs but decreased in *Rev1*^{-/-} MEFs relative to untreated cells. These data are consistent with the idea that *Rev1*-deficient cells display mitochondrial dysfunction and a defect in autophagy, which could reflect de-regulation of upstream signals including LKB1 and Sirtuin-1 (SIRT1).

***Rev1*-deficiency affects mitochondrial function through PARP-NAD⁺-SIRT1-PGC1 α axis.** SIRT1 is a class III histone deacetylase (HDAC), which requires NAD⁺ for activity. Deacetylation of target proteins by SIRT1 can either enhance or decrease their activity or stability⁵². SIRT1 deacetylates a number of target proteins including LKB1 and PGC1 α . Deacetylation of LKB1 by SIRT1 promotes its activity and the phosphorylation of AMPK α at Thr172^{52–55}. We investigated expression of SIRT1 in WT and *Rev1*^{-/-} MEFs and observed decreased abundance of SIRT1 in *Rev1*^{-/-} MEFs (Fig. 5a,b) as well as a significantly lower level of NAD⁺ in *Rev1*^{-/-} MEFs than in WT MEFs (Fig. 5c). These data suggest that low abundance of SIRT1 and NAD⁺ leads to low AMPK activity in *Rev1*-deficient cells.

PARP1 is a component of DDR that detects and binds to abnormal and damaged DNA^{9,10,56}. Upon binding, PARP1 synthesizes and attaches poly(ADP-ribose) polymers (PAR) on its protein substrates. PARP1 also auto-PARylates itself, thus, PARP1 can be a major consumer of intracellular NAD⁺^{10,56,57} and it can impair mitochondrial function⁵⁸. The PARP1 expression is significantly increased in *Rev1*^{-/-} MEFs (Fig. 5d,e). To test whether decrease in NAD⁺ level is responsible for mitochondrial dysfunction in *Rev1*^{-/-} cells, we treated the MEF cells with 3 mM Nicotinamide riboside (NR), a NAD⁺ precursor (Figure S8). NR treatment enhanced mitochondrial function and increased the reserve capacity to the level of untreated *Rev1*^{+/+} cells. This suggests that impaired mitochondrial function in *Rev1*^{+/+} cells is caused by NAD⁺ depletion and NR supplement can suppress this defect.

Here, we propose that defects in *Rev1* could increase the load of persistent DNA lesions and thus lead to constitutive activation of PARP1. It has previously been proposed that such a pathway reflects “nuclear to mitochondrial DNA damage signaling”⁷. Our results are consistent with activation of such a pathway in *Rev1*-deficient cells, because the abundance of PARP1 is significantly higher in *Rev1*^{-/-} MEFs than in WT MEFs (Fig. 5d,e).

Discussion

This study examines whether and how murine *Rev1* might play a direct role in or modulate mitochondrial function(s) and cellular bioenergetics. Our data are consistent with the idea that *Rev1*-deficiency leads to replicative stress, which may in turn lead to constitutive activation of DDR and PARP1, decreased abundance of NAD⁺, and low SIRT1 and AMPK activities. Similar observations were recently made in other DNA repair deficient cells, and this set of related observations was referred to in that context as the “PARP-NAD⁺-SIRT1-PGC1 α axis”⁷ (Fig. 6).

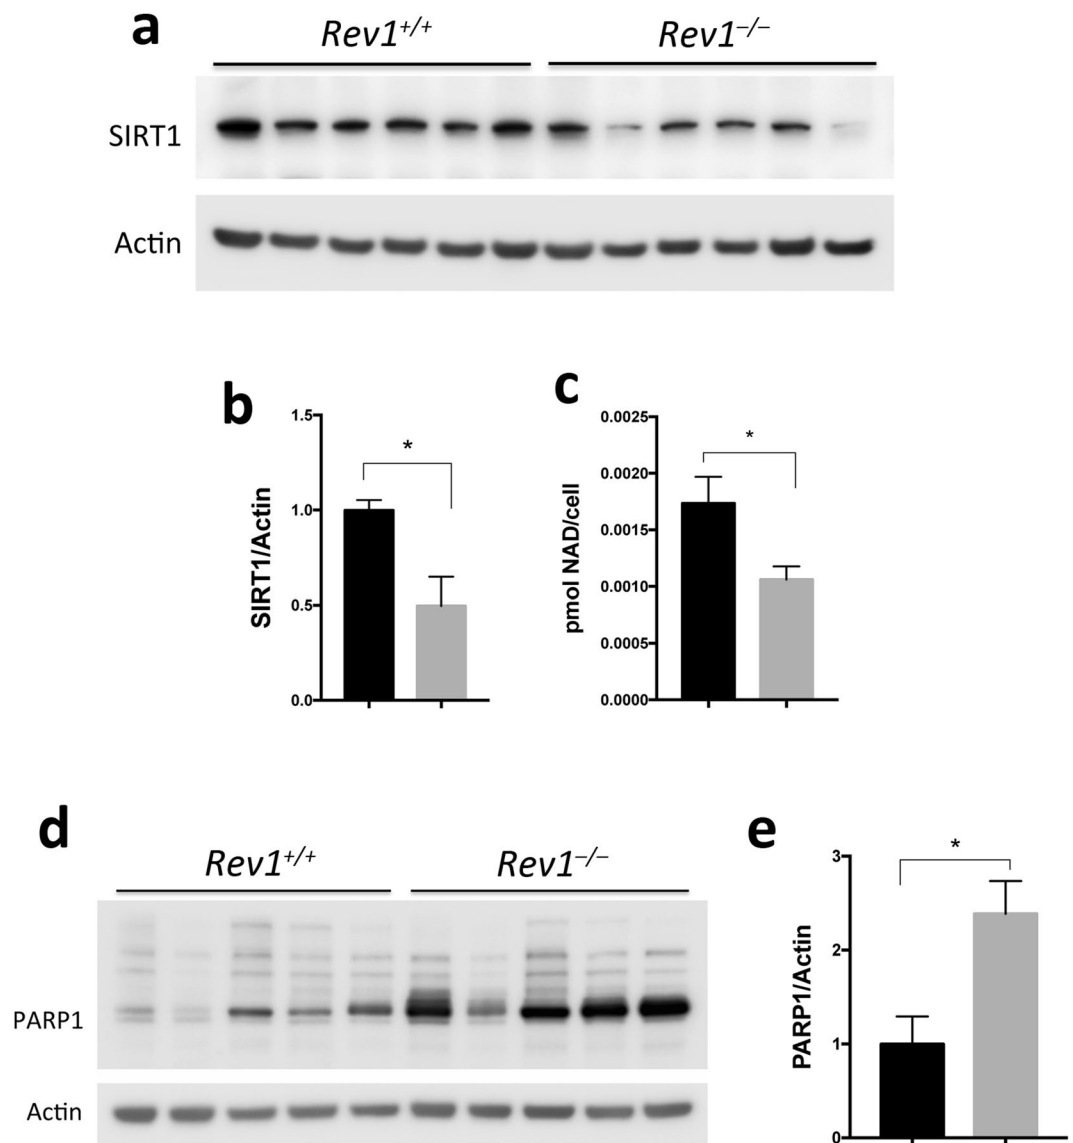

Figure 5. Cellular SIRT1 protein and NAD⁺ levels are decreased while the PARP1 protein level is increased in *Rev1*^{-/-} MEFs. **(a)** Immunoblot analysis of SIRT1 in MEFs in 6 biological replicates ($n = 6$; $t = 3.457$; $df = 5$). **(b)** Quantification of protein levels shown in panel **(a)**. **(c)** Relative NAD⁺ (NAD⁺/NADH) level in WT and *Rev1*^{-/-} MEFs ($n = 6$, $t = 3.161$, $df = 10$). **(d)** Immunoblot analysis of PARP1 in WT and *Rev1*^{-/-} MEF cell extracts in several biological replicates ($n = 5$, $t = 4.251$, $df = 4$). **(e)** Quantification of protein levels shown in panel **(d)**. $n =$ sample number; $t =$ t value; $df =$ degree of freedom; * $p < 0.05$. ** $p < 0.01$. *** $p < 0.001$. **** $p < 0.0001$. Data presented are mean \pm M.S.E. Dark bars: WT and gray bars: *Rev1*^{-/-}.

Rev1-deficient cells are unable to bypass the damaged bases and replication stress is higher in these cells⁵⁹. *Rev1*^{-/-} cells accumulate single stranded gaps opposite the DNA lesions, which induce DNA damage signaling and irreversible G2 arrest¹³. In response to DNA damage and DDR activation, cells increase mitochondrial respiration and OXPHOS activity to increase ATP⁶⁰.

The altered mitochondrial morphology, decreased mitophagy, increased basal and ATP linked respiration as well as increased MMP and mitochondrial ROS in *Rev1*^{-/-} suggests that ATP production may be higher in these cells than in WT controls,^{30,31,37,61}. However, we observed that total ATP was nearly 2-fold lower in *Rev1*^{-/-} than in WT control cells. This indicates that ATP consumption exceeds ATP production in *Rev1*^{-/-} MEFs as these cells are constantly under replication stress⁵⁹. In addition, we observed that the PARP1 expression is increased and the NAD⁺ level is decreased in *Rev1*-deficient cells, which can impair mitochondrial function, mitophagy and ATP synthesis^{7,11,58}. Interestingly, we could suppress the decreased mitochondrial reserve capacity in *Rev1*^{-/-} MEFs by addition of the NAD⁺ precursor NR (Figure S8). This supports the axis, Fig. 6, where the decreased levels of NAD lead to mitochondrial dysfunction, and this can at least partially be restored by NAD supplementation.

Despite a significant decrease in abundance of ATP, AMPK activity was lower in *Rev1*^{-/-} cells. This is an important observation, because AMPK is required to inhibit Akt-mTOR^{62,63}, and to activate mitophagy/

Figure 6. The “PARP-NAD⁺-SIRT1-PGC1 α axis”. Replication stress can cause mitochondrial dysfunction by downstream changes in various cellular pathways. A number of factors contribute to this signaling, such as poly(ADP-ribose) polymerase 1 (PARP1), ataxia telangiectasia mutated (ATM), ataxia telangiectasia and Rad3-related protein (ATR), and the transcription factor p53. The NAD-dependent protein deacetylase sirtuin 1 (SIRT1) and the transcription regulator AMP-activated protein kinase (AMPK) then propagate the signal through post-translational modifications (deacetylation or phosphorylation, respectively) of peroxisome proliferator-activated receptor- γ co-activator 1 α (PGC1 α) and other proteins. The figure is adapted from Fang *et al.* 2016⁷.

autophagy in response to replicative or other forms of chronic stress. In addition, increased Akt activity negatively regulates the SOD2 expression⁶⁴.

Despite a significant increase in total DRP1 and pDRP1 ser616 in Rev1-deficient MEFs, these cells appear to accumulate elongated mitochondria with aberrant morphological features. This could reflect the low level of activated AMPK in Rev-1 deficient cells, because activated AMPK stimulates MFF, promotes oligomerization of DRP1 on the surface of mitochondria, and stimulates mitophagy⁵¹. Decreased AMPK phosphorylation can be explained by the decrease in SIRT1 protein level and perhaps its activity as NAD⁺ level was decreased in Rev1^{-/-} MEFs⁵³⁻⁵⁵. As treatment with AICAR did not rescue mitochondrial dysfunction in Rev1-deficient cells, we conclude that signals downstream of AMPK, such as SIRT1 and LKB1, may be suppressed or dysfunctional in Rev1^{-/-} MEFs.

In conclusion, the results presented here suggest that Rev1-deficient MEFs and liver tissue may experience persistent replication stress and DDR, which leads to metabolic stress caused by mitochondrial dysfunction, mediated by the so-called “PARP-NAD⁺-SIRT1-PGC1 α axis”⁹⁷ (Fig. 6). In addition, our results suggest that AMPK may also tie into the “PARP-NAD⁺-SIRT1-PGC1 α axis”, and suppression of its activity could exacerbate mitochondrial dysfunction in these cells.

Materials and Methods

Animals and Cells. WT and Rev1^{-/-} mice and MEF cells were provided by Dr. Niels de Wind from the department of human genetics at Leiden University Medical Center (LUMC). All procedures involving animals were approved by the Danish National Ethics Committee according to the guidelines set forth in the European Council’s Convention for the Protection of Vertebrate Animals used for Experimental and Other Scientific Purposes. Mice were randomized and marked with special ear cuts for later identification. WT and Rev1^{-/-} mice and MEFs were genotyped as described before⁶⁵. We excluded mouse 7 (due to being heterozygous) and 9 (for being sick and moribund) (Figure S5a). Sex determination by PCR in mice was performed as described⁶⁶. Mice

were sacrificed by cervical dislocation and the liver, kidneys, heart and brain were removed. MEF cells cultured in Dulbecco's Modified Eagle Medium (DMEM) plus 10% (v/v) fetal calf serum (Invitrogen) and 100 U/mL penicillin-streptomycin in a humidified atmosphere of 5% CO₂ at 37 °C. All the experiments are carried out latest two weeks after the initiation of the cell culture or as stated.

Isolation of Mitochondria from the Mice Liver. Mitochondria from WT and *Rev1*^{-/-} mice aged 5 months were isolated by centrifugation methods as described⁶⁷. The liver was extracted and sliced in MSHE+BSA (4 °C), and all subsequent steps of the preparation were performed on ice. The material was rinsed several times to remove blood. The tissue was disrupted using a drill-driven Teflon glass homogenizer with 2–3 strokes. Homogenate was centrifuged at 800 × g for 10 min at 4 °C. Following centrifugation, fat/lipid was carefully removed, and the remaining supernatant was decanted through 2 layers of cheesecloth to a separate tube and centrifuged at 8000 × g for 10 min at 4 °C. After removal of the mitochondrial layer, the pellet was resuspended in MSHE+BSA, and the centrifugation was repeated. The final pellet was resuspended in a minimal volume of MSHE+BSA. Total protein (mg/ml) was determined using Bradford Assay reagent (Bio-Rad).

Cellular bioenergetics and citrate synthase assay. All XF assays were performed using an XF24 Extracellular Flux Analyzer (Seahorse Bioscience):

MEF cells. Oxygen consumption rate and cellular acidification rate in MEF cells measured according to the manufacturer procedure. Briefly, 5 × 10⁴ cells/well seeded on the seahorse plate 12 hrs before the experiment. For the AICAR treatment, cells were treated with AICAR (0.25 mM) for 96 hrs prior to the experiment. Total protein was extracted from the cells in each well and protein concentrations determined by Bradford. The basal respiration was normalized to the protein content of each well.

Isolation of mitochondria from liver. Respiration of isolated liver mitochondria was determined with a Seahorse XF24 Analyzer. The isolation procedure was performed on ice. Liver was excised and immersed in ice-cold mitochondrial isolation buffer (MSHE; in mM: sucrose 70; mannitol 210; HEPES 5 and EGTA 1, pH 7.0) + 0.5% (w/v) fatty acid-free BSA and homogenized in a dounce type teflon-on-glass homogenizer. The homogenate was centrifuged 5 min at 900 × g. The supernatant was collected, while avoiding top layer of fat, and transferred to Eppendorf tubes and centrifuged for 10 min at 9000 × g. Following centrifugation, fat was carefully removed and pellet was resuspended in MSHE buffer where after the suspension was centrifuged for 10 min at 10,000 × g. The pellet was re-suspended in MSHE. Protein concentration was determined spectrophotometrically at 595 nm by addition of 5 μl diluted mitochondrial suspension and 250 μl Bio-Rad (Hercules, CA, USA) Protein Assay Dye reagent. BSA was used as standard protein.

Determination of parameters of oxidative phosphorylation of isolated liver mitochondria. The suspension of isolated mitochondria was diluted in supplemented MSHE (10 mM succinate + 2 μM rotenone for coupling assay and 10 mM pyruvate + 2 mM malate + 4 μM FCCP for electron flow assay) and added to a final concentration of 5 μg to each well in a 24-well Seahorse plate. The plate was centrifuged at 2,000 × g for 10 min at RT. Mitochondrial assay solution (MAS; in mM: sucrose 70; mannitol 220; KH₂PO₄ 10; MgCl₂ 5; HEPES 2 and EGTA 1; pH 7.0) was added and the plate was transferred to the XF24 Seahorse at 37 °C. For monitoring mitochondrial respiration the measurement cycle consisted of 1 min mixing and one measurement cycle (each measurement cycle reflects an average of ten measurements) before addition of first inhibitor/substrate compound (40 mM ADP for coupling assay, 20 μM rotenone for electron flow assay), then another measurement cycle and injection of second compound (3 μM oligomycin for coupling assay, 0.1 M succinate for electron flow assay), and another two cycles after injection of third compound (4 μM FCCP for coupling assay, 40 μM antimycin A for electron flow assay), and fourth compound (40 μM antimycin A for coupling assay, 100 mM ascorbate + 1 mM TMPD for electron flow assay) respectively. Each point represents an average of a minimum of 3 replicate wells and each condition was repeated a minimum of 5 times.

Citrate synthase activity assay on liver homogenate. The citrate synthase activity (CS) assay was determined as described⁶⁸ with minor modifications. All steps were done on ice and centrifugation steps at 4 °C. Liver tissue was immersed in ice cold MSHE buffer after excision, and washed with MSHE buffer to remove blood. The liver tissue was snap frozen in liquid nitrogen and stored at -80 °C. 30–50 mg of tissue was used for CS assay. Visible fat was removed and liver tissue was minced with scissors before dilution in 5 ml MSHE + 0.5% fatty acid free BSA buffer in a 1-ml douncer with a teflon-on-glass homogenizer. The homogenate was centrifuged at 10 min for 600 × g, and the supernatant was transferred to a new tube and centrifuged at 10 min for 7000 × g. The supernatant was discarded and pellet resuspended in remaining buffer. In a 1-ml quartz cuvette the following things were mixed: 300 μl distilled water, 500 μl Tris (200 mM, pH 8.0) with 0.2% Triton X-100 (v/v), 100 μl DTNB (5,5'-Dithiobis(2-nitrobenzoic acid, 1mM), 30 μl of Acetyl-coenzyme A lithium salt (10 mM) and 60 μg liver tissue. The baseline activity was read at absorbance 412 nm for 2 min, hereafter the reaction was started by 50 μl of oxaloacetic acid 10 mM, and the increase in absorbance was monitored for 3 min. Activity was measured as ((ΔAbsorbance/min) × 1000)/(13.6 × sample(ml) × protein concentration (mg/ml)). All the reagents were from Sigma-Aldrich.

Isolation of genomic DNA and mtDNA quantification. Genomic DNA (gDNA), RNA and protein were extracted from snap frozen tissues in liquid nitrogen, using Norgen Biotik RNA/DNA Purification Kit (Cat. 48700) according to the manufacturer's protocol. Quantitative PCR (two independent reactions) was used for measurement of mtDNA⁶⁹ using SYBR Green PCR Master mix (Applied Biosystems). The mtDNA copy number normalized to nuclear DNA was measured as the ratio of DNA encoding the mitochondrial

gene for murine tRNA leucine 1 (*Trnl1*) to DNA encoding the nuclear gene encoding Beta-2 microglobulin (*B2m*). The following primers were used: *B2m* forward, 5'-GTCAGATATGCTTCAGCAAG-3', and reverse, 5'-CTTCAACTCTGCAGGCGTATG-3'; and *Trnl1* forward, 5'-AAGGTTATTAGGGTGGCAG-3', and reverse, 5'-GGACGAGGAGTGTAGGATA-3'. For PCR reaction mixture 5 ng of genomic DNA was mixed with 2 μ l of each primers (5 μ M), 10 μ l SYBR green and 0.4 μ l ROX and nuclease free water to the final volume of 20 μ l. All reactions were run in triplicates. The relative mtDNA levels were calculated using formula $2 \times 2^{\Delta\text{CT}}$.

Immunoblot analysis. The frozen liver tissues were ground in liquid nitrogen prior to incubation with RIPA (Sigma) supplemented with supplemented with cOmplete™, EDTA-free Protease Inhibitor Cocktail (Sigma) and PhosSTOP phosphatase inhibitor Cocktail (Sigma). MEFs cells and grinded tissue were re-suspended in RIPA (Sigma) supplemented with supplemented with cOmplete™, EDTA-free Protease Inhibitor Cocktail (Sigma) and PhosSTOP phosphatase inhibitor Cocktail (Sigma). The cell suspension was left on ice for 30 min followed by sonication and then left on ice for another 15 min. Subsequently, the cell suspension was centrifuged at 20K G-force for 20 min and the supernatant was mixed with NuPAGE® LDS Sample Buffer (4X) (Thermo Fisher Scientific). For gel electrophoresis, the supernatants was denatured at 70 °C (50 °C for mitochondrial complexes analyses) for 10 min and 20 to 30 μ g protein was loaded on NuPAGE™ Novex™ 4–12% Bis-Tris Protein Gels, 1.0 mm (Thermo Fisher Scientific) and run according to the manufacturer's instructions.

Antibodies used in this study: pan-Actin (Thermo Fisher Scientific MA5-11869) (1:20000); AMPK α 1 (Santa Cruz bio. Sc-19128) (1:500); Phospho-AMPK α (Thr172)(Cell signaling #2531) (1:1000); COX4 (Santa Cruz bio. Sc-69360) (1:2000); DRP1 (Cell signaling #8570) (1:1000); Phospho-DRP1 (Ser616) (Cell signaling #3455) (1:1000); Lamin B1 (Abcam ab133741) (1:10000); LC3B/MAP1LC3B (Novus Biologicals, NB100-2220) (1:1000); Total OXPHOS Rodent WB Antibody Cocktail (Abcam, ab110413) (1:1000); PARP (Cell signaling, #9542) (1:1000); PGC1 α (Novus Biologicals, NBP1-04676) (1:3000); SIRT1 (Santa Cruz bio, sc-15404) (1:500); SOD2 (Cell signaling, #13194) (1:1000).

Measurements mitochondrial membrane potential and ROS. Mitochondrial membrane potential and ROS were measured as described elsewhere using MitoSOX Red and TMRM (Thermo Fisher Scientific) respectively⁷⁰. Briefly, 0.7×10^5 cells/well were seeded in six well plates less than 48 hrs before initiation of the experiment. Cells were washed with Dulbecco's Phosphate-Buffered Saline (DPBS) and treated with 5 μ M MitoSOX Red for 15 min and 40 μ M TMRM for 20 min prior to FACS analysis. MitoSOX Red-positive cells were counted using a FACScan™ flow cytometer (Becton Dickinson). For live cell fluorescent imaging of MMP, approximately 2×10^5 cells/6cm culture dish seeded 24h before the experiment. Treated cell were incubated with 2 μ M rotenone for 5h in complete medium. After treatment cells were washed with PBS and incubated with 40 nM TMRM in serum free medium for 30 minutes. After staining cells were washed and incubated with serum free media for live cell imaging using confocal microscopy (Zeiss Confocal microscope LSM 780).

ATP and NAD⁺/NADH Quantitation. ATP concentration was detected using an ATPlite Luminescence Assay System (PerkinElmer) according to the manufacturer's instruction. Briefly, cells were plated in a 96-well plate (10^5 cells in 100 μ l/well) for 24 hrs before the ATP consumption assay. After this time, 50 μ l lysis buffer was added followed by addition of substrate. Luminescence was measured on the FLUOstar OPTIMA Microplate reader (BMG LABTECH). Measurement of NAD⁺ is performed using SIGMA NAD/NADH Quantitation kit (MAK037) according to the manufacturer protocol. Briefly, 2×10^4 cells harvested for total NAD extraction and quantification. The NAD Cycling Enzyme Mix in the kit recognizes NADH and NAD, but not NADP or NADPH, in an enzyme cycling reaction. Concentration of NAD total (NADt) (NAD⁺ + NADH) is determined by measuring the absorbance at (OD 450 nm). The NAD⁺ concentration is calculated by subtracting the NADH values from NADt. In Some *Rev1*^{-/-} samples, the NADH concentration was below the detection range. We perceived the NADH concentration in these samples as zero (0).

Colony forming assay. For the cell survival assay, 700 cells were seeded in 100 mm culture dishes. After 24 hrs, different concentrations of menadione (0, 5, 10, 15, and 20 μ M) were added to the cell culture. The cultures were maintained until colonies were visible. The colonies were then fixed and stained with crystal violet in 20% ethanol, and colonies with more than 50 cells, were counted as a colony.

Detection of Autophagy and Mitophagy. Analysis of autophagy/mitophagy was carried out by detecting the LC3-II/actin ratio⁷¹. Briefly, 7×10^5 cells/dish were seeded on 10 cm cell culture dishes. The following day, mitophagy was induced by treatment with 2 and 4 μ M rotenone for 12 hrs. After this time, cells were harvested and prepared for immunoblotting. We used a commercially mitophagy kit (Dojindo Laboratories) to assess the rate of mitophagy as described by provider. About 2×10^5 cells were seeded on cover slips in 6 cm culture dishes 24 h before the live imaging. The next day, cells were washed twice with PBS and serum free media. The mitophagy dye diluted to the recommended working concentration (100 nM/l) in serum free media and cells incubated for 30 min. The media and dye was removed and cells were washed twice with PBS and serum free media. Next, Cells were incubated with complete media containing 2 μ M rotenone for 5h. After 5h, the intensity of mitophagy dye was asses using confocal microscopy (Zeiss Confocal microscope LSM 780). Pictures were analyzed using image J software.

Transfection, fluorescence microscopy. Transfection of the YFP-Rev1 fusion protein into *Rev1*^{-/-} MEF cells was performed using Lipofectamine® 3000 reagent (Life technologies) according to the manufacturer procedure. Briefly, 3×10^5 cells/well were seeded in 6 well plates 18 hrs before the transfection. Cells were transfected with 2.5 μ g of plasmid DNA per well in complete medium. Transfected cells were visualized with an inverted fluorescence microscope (Nikon). MitoTracker staining (Molecular Probes) was performed in live MEFs and analyzed by fluorescent microscopy after fixation with 4% formaldehyde.

Electron microscopy. *Mice Livers.* For transmission electron microscopy studies small blocks (typically 0.5 mm × 0.5 mm × 1 mm) from the liver from WT and *Rev1*^{-/-} mice, perfusion-fixed with 4% paraformaldehyde and 0.1 glutaraldehyde in phosphate buffer were cryoprotected in glycerol and freeze substituted with Lowicryl HM20 as described⁷². Ultrathin sections were cut (90 nm) using a diamond knife and dried at room temperature followed by counterstaining with 1% uranyl acetate and 0.3% lead citrate. Electron micrographs were taken with a FEI Tecnai 12 transmission electron microscope at primary magnifications of ×6000.

MEF Cells. Cells were seeded on the Thermanox™ coverslips (Thermoscientific) in 12 well plates at the concentration of 5 × 10⁴ cells/well. When the cells became confluent, they were washed with PBS, and fixed in 2% glutaraldehyde/0.1 M sodium cacodylate buffer (pH 7.4) at room temperature for 1 hr. Cells were washed twice in PBS and postfixed in 2% OsO₄/PBS at room temperature for 1 hr, dehydrated in ethanol and embedded in Epon (Serva, Heidelberg, Germany). Thin sections of 50 nm were contrasted with uranylacetate and lead citrate, and examined using a transmission electron microscope (Tecnai G2 20 TWIN).

Statistical analysis. Prism 7.0 (GraphPad Software) was used to plot data, make graphs, and statistical analysis. Data are plotted as mean ± SEM. Two-tailed paired and unpaired Student's t-test was performed for MEFs and liver cells.

Acknowledgements

A.M.-P., N.D.W., N.B.F., and L.J.R. were supported by the EU/Marie Curie/Marriage I.T.N. J.A.D., C.D., and L.J.R. were supported by the Danish Research Council. N.B.F., J.A.D., C.D., L.H.B., M.L., and L.J.R. additionally were supported by Nordea-fonden.

Author Contributions

N.D.W., M.L., L.H.B., V.B., N.B.F. and L.J.R. designed and supervised the experiments and interpreted the results. N.B.F. and L.J.R. wrote the manuscript. N.B.F., J.A.D., C.E.R., M.A., C.D., M.D.M.H.-O., A.M.-P., A.T.-S., and K.T. carried out experiments and interpreted the results. N.B.F. performed the majority of experiments. All authors edited the manuscript.
