27

**Abstract** Response inhibition is essential for navigating everyday life. Its derailment is considered integral to numerous neurological and psychiatric disorders, and more generally, to a wide range of behavioral and health problems. Response-inhibition efficiency furthermore correlates with treatment outcome in some of these conditions. The stop-signal task is an essential tool to determine how quickly response inhibition is implemented. Despite its apparent simplicity, there are many features (ranging from task design to data analysis) that vary across studies in ways that can easily compromise the validity of the obtained results. Our goal is to facilitate a more accurate use of the stop-signal task. To this end, we provide twelve easy-to-implement consensus recommendations and point out the problems that can arise when these are not followed.

37 Furthermore we provide user-friendly open-source resources intended to inform statistical-power  
38 considerations, facilitate the correct implementation of the task, and assist in proper data analysis.

39

## 40 Introduction

41 The ability to suppress unwanted or inappropriate actions and impulses ('response inhibition') is a  
42 crucial component of flexible and goal-directed behavior. The stop-signal task (*Lappin and Eriksen,*  
43 *1966; Logan and Cowan, 1984; Vince, 1948*) is an essential tool for studying response inhibition in  
44 neuroscience, psychiatry, and psychology (among several other disciplines; see Appendix 1), and  
45 is used across various human (e.g. clinical vs. non-clinical, different age groups) and non-human  
46 (primates, rodents, etc.) populations. In this task, participants typically perform a go task (e.g.  
47 press left when an arrow pointing to the left appears, and right when an arrow pointing to the  
48 right appears), but on a minority of the trials, a stop-signal (e.g. a cross replacing the arrow)  
49 appears after a variable stop-signal delay (SSD), instructing participants to suppress the imminent  
50 go response (Figure 1). Unlike the latency of go responses, response-inhibition latency cannot  
51 be observed directly (as successful response inhibition results in the absence of an observable  
52 response). The stop-signal task is unique in allowing the estimation of this covert latency (stop-  
53 signal reaction time or SSRT; Box 1). Research using the task has revealed links between inhibitory-  
54 control capacities and a wide range of behavioral and impulse-control problems in everyday life,  
55 including attention-deficit/hyperactivity disorder, substance abuse, eating disorders, and obsessive-  
56 compulsive behaviors (for meta-analyses, see e.g. ???).

57 Today, the stop-signal field is flourishing like never before (see Appendix 1). There is a risk,  
58 however, that the task falls victim to its own success, if it is used without sufficient regard for a  
59 number of important factors that jointly determine its validity. Currently, there is considerable  
60 heterogeneity in how stop-signal studies are designed and executed, how the SSRT is estimated,  
61 and how results of stop-signal studies are reported. This is highly problematic. First, what might  
62 seem like small design details can have an immense impact on the nature of the stop process  
63 and the task. The heterogeneity in designs also complicates between-study comparisons, and  
64 some combinations of design and analysis features are incompatible. Second, SSRT estimates are  
65 unreliable when inappropriate estimation methods are used or when the underlying race-model  
66 assumptions are (seriously) violated (see Box 1 for a discussion of the race model). This can lead to  
67 artefactual and plainly incorrect results. Third, the validity of SSRT can be checked only if researchers  
68 report all relevant methodological information and data.

69 Here we aim to address these issues by consensus. After an extensive consultation round,  
70 the authors of the present paper agreed on twelve recommendations that should safeguard and  
71 further improve the overall quality of future stop-signal research. The recommendations are based  
72 on previous methodological studies or, where further empirical support was required, on novel  
73 simulations (which are reported in Appendices 2–3). A full overview of the stop-signal literature  
74 is beyond the scope of this study (but see e.g. ?????, for comprehensive overviews of the clinical,  
75 neuroscience, and cognitive stop-signal domains; see also the meta-analytic reviews mentioned  
76 above)

77 Below, we provide a concise description of the recommendations. We briefly introduce all  
78 important concepts in the main manuscript and the boxes. Appendix 4 provides an additional  
79 systematic overview of these concepts and their common alternative terms. Moreover, this article  
80 is accompanied by novel open-source resources that can be used to execute a stop-signal task and  
81 analyze the resulting data, in an easy-to-use way that complies with our present recommendations  
82 (<https://osf.io/rmqaw/>). The source code of the simulations (Appendices 2–3) is also provided,  
83 and can be used in the planning stage (e.g. to determine the required sample size under varying  
84 conditions, or acceptable levels of go omissions and RT distribution skew).

86

### Box 1. The independent race model

87

88

89

90

91

Here we provide a brief discussion of the independent race model, without the specifics of the underlying mathematical basis. However, we recommend that stop-signal users read the original modelling papers (e.g. *Logan and Cowan, 1984*) to fully understand the task and the main behavioral measures, and to learn more about variants of the race model (e.g. *Boucher et al., 2007; Colonius and Diederich, 2018; Logan et al., 2014, 2015*)

92

93

97

98

99

100

101

102

103

Response inhibition in the stop-signal task can be conceptualized as an independent race between a 'go runner', triggered by the presentation of a go stimulus, and a 'stop runner', triggered by the presentation of a stop signal (*Logan and Cowan, 1984*). When the 'stop runner' finishes before the 'go runner', response inhibition is successful and no response is emitted (*successful stop trial*); but when the 'go runner' finishes before the 'stop runner', response inhibition is unsuccessful and the response is emitted (*unsuccessful stop trial*). The independent race model mathematically relates (a) the latencies (RT) of responses on unsuccessful stop trials; (b) RTs on go trials; and (c) the probability of responding on stop-signal trials [ $p(\text{respond} | \text{stop signal})$ ] as a function of stop-signal delay (yielding 'inhibition functions'). Importantly, the independent race model provides methods for estimating the covert latency of the stop process (stop-signal reaction time; SSRT). These estimation methods are described in Materials and Methods.

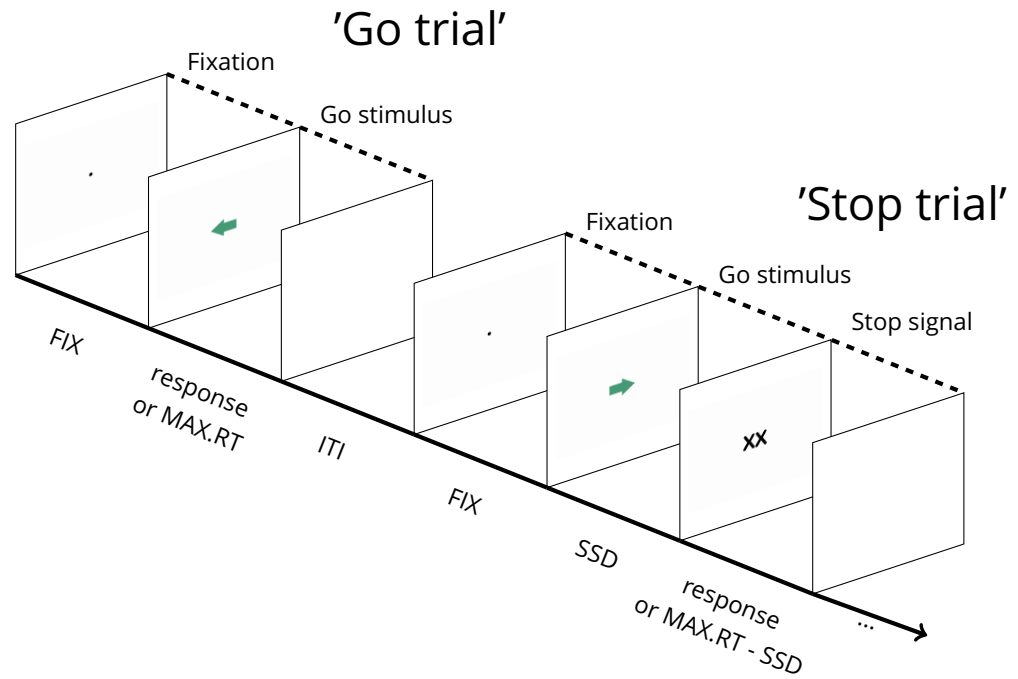

104

105

106

**Box 1 Figure 1.** The independent race between go and stop.

**Figure 1.** Depiction of the sequence of events in a stop-signal task (see <https://osf.io/rmqaw/> for open-source software to execute the task). In this example, participants respond to the direction of green arrows (by pressing the corresponding arrow key) in the go task. On one fourth of the trials, the arrow is replaced by 'XX' after a variable stop-signal delay (FIX = fixation duration; SSD = stop-signal delay; MAX.RT = maximum reaction time; ITI = intertrial interval).

## 107 Results and Discussion

108 The following recommendations are for stop-signal users who are primarily interested in obtaining  
 109 a reliable SSRT estimate under standard situations. The stop-signal task (or one of its variants) can  
 110 also be used to study various aspects of executive control (e.g. performance monitoring, strategic  
 111 adjustments, or learning) and their interactions, for which the design might have to be adjusted.  
 112 However, researchers should be aware that this will come with specific challenges (e.g. *Bissett and*  
 113 *Logan, 2014; Nelson et al., 2010; Verbruggen et al., 2013; Verbruggen and Logan, 2015*).

### 114 How to design stop-signal experiments

#### 115 Recommendation 1: Use an appropriate go task

116 Standard two-choice reaction time tasks (e.g. in which participants have to discriminate between  
 117 left and right arrows) are recommended for most purposes and populations. When very simple  
 118 go tasks are used, the go stimulus and the stop signal will closely overlap in time (because the  
 119 SSD has to be very short to still allow for the possibility to inhibit a response), leading to violations  
 120 of the race model as stop-signal presentation might interfere with encoding of the go stimulus.  
 121 Substantially increasing the difficulty of the go task (e.g. by making the discrimination much harder)  
 122 might also influence the stop process (e.g. the underlying latency distribution or the probability  
 123 that the stop process is triggered). Thus, very simple and very difficult go tasks should be avoided  
 124 unless the researcher has theoretical or methodological reasons for using them<sup>1</sup>. While two-choice  
 125 tasks are the most common, we note that the 'anticipatory response' variant of the stop-signal task  
 126 (in which participants have to press a key when a moving indicator reaches a stationary target) also

<sup>1</sup>For example, simple detection tasks have been used in animal studies. To avoid responses before the go stimulus is presented or close overlap between the presentation of go stimulus and stop signal, the intertrial interval can be drawn from a random exponential distribution. This will make the occurrence of the go stimulus unpredictable, discouraging anticipatory responses.

127 holds promise (e.g. *Leunissen et al., 2017*).

128 Recommendation 2: Use a salient stop signal

129 SSRT is the overall latency of a chain of processes involved in stopping a response, including the  
130 detection of the stop signal. Unless researchers are specifically interested in such perceptual  
131 or attentional processes, salient, easily detectable stop signals should be used <sup>2</sup>. Salient stop  
132 signals will reduce the relative contribution of perceptual (afferent) processes to the SSRT, and the  
133 probability that within- or between-group differences can be attributed to them. Salient stop signals  
134 might also reduce the probability of a 'trigger failures' on stop trials (see Box 2).

135 Recommendation 3: Present stop signals on a minority of trials

136 When participants strategically wait for a stop signal to occur, the nature of the stop-signal process  
137 and task change (complicating the comparison between conditions or groups; e.g. SSRT group  
138 differences might be caused by differential slowing or strategic adjustments). Importantly, SSRT  
139 estimates will also become less reliable when participants wait for the stop-signal to occur (*Ver-*  
140 *bruggen et al., 2013*, see also Figure 2 and Appendix 2). Such waiting strategies can be discouraged  
141 by reducing the overall probability of a stop signal. For standard stop-signal studies, 25% stop  
142 signals is recommended. When researchers prefer a higher percentage of stop signals, additional  
143 measures to minimize slowing are required (see Recommendation 5).

144 Recommendation 4: Use the tracking procedure to obtain a broad range of stop-signal  
145 delays

146 If participants can predict when a stop signal will occur within a trial, they might also wait for it.  
147 Therefore, a broad range of SSDs is required. The stop-signal delay can be continuously adjusted via  
148 a standard adaptive tracking procedure: SSD increases after each successful stop, and decreases  
149 after each unsuccessful stop; this converges on a probability of responding [ $p(\text{respond} | \text{stop signal})$ ]  
150  $\approx .50$ . Many studies adjust SSD in steps of 50 ms (which corresponds to three screen 'refreshes' for  
151 60-Hz monitors). When step size is too small – e.g. 16 ms – the tracking may not converge in short  
152 experiments, whereas it may not be sensitive enough if step size is too large. Importantly, SSD  
153 should decrease after *all* responses on unsuccessful stop trials; this includes premature responses  
154 on unsuccessful stop trials (i.e. responses executed before the stop signal was presented) and  
155 choice errors on unsuccessful stop trials (e.g. when a left go response would have been executed  
156 on the stop-signal trial depicted in Figure 1, even though the arrow was pointing to the right).

157 An adaptive tracking procedure typically results in a sufficiently varied set of SSD values. An  
158 additional advantage of the tracking procedure is that fewer stop-signal trials are required to obtain  
159 a reliable SSRT estimate (*Band et al., 2003*). Thus, the tracking procedure is recommended for  
160 standard applications.

161 Recommendation 5: Instruct participants not to wait and include block-based feedback

162 In human studies, task instructions should also be used to discourage waiting. At the very least,  
163 participants should be told that "*[they] should respond as quickly as possible to the go stimulus and not*  
164 *wait for the stop signal to occur*" (or something along these lines). To adults, the tracking procedure  
165 (if used) can also be explained to further discourage a waiting strategy (i.e. inform participants that  
166 the probability of an unsuccessful stop trial will approximate .50, and that SSD will increase if they  
167 gradually slow their responses).

168 Inclusion of a practice block in which adherence to instructions is carefully monitored is recom-  
169 mended. In certain populations, such as young children, it might furthermore be advisable to start  
170 with a practice block without stop signals to emphasize the importance of the go component of the  
171 task.

<sup>2</sup>When auditory stop signals are used, these should not be too loud either, as very loud (i.e. >80 dB) auditory stimuli may produce a startle reflex.

172 Between blocks, participants should also be reminded about the instructions. Ideally, this is  
 173 combined with block-based feedback, informing participants about their mean RT on go trials,  
 174 number of go omissions (with a reminder that this should be 0), and  $p(\text{respond} | \text{signal})$  (with a  
 175 reminder that this should be close to .50). The feedback could even include an explicit measure of  
 176 response slowing.

#### 177 Recommendation 6: Include sufficient trials

178 The number of stop-signal trials varies widely between studies. Our novel simulation results (see  
 179 Figure 2 and Appendix 2) indicate that reliable and unbiased SSRT group-level estimates can be  
 180 obtained with 50 stop trials<sup>3</sup>, but only under 'optimal' or very specific circumstances (e.g. when  
 181 the probability of go omissions is low and the go-RT distribution is not strongly skewed). Lower  
 182 trial numbers (here we tested 25 stop signals) rarely produced reliable SSRT estimates (and the  
 183 number of excluded subjects – see Figure 2 – was much higher). Thus, as a general rule of thumb,  
 184 we recommend to have at least 50 stop signals for standard group-level comparisons. However, it  
 185 should again be stressed that this may not suffice to obtain reliable individual estimates (which are  
 186 required for e.g. individual-differences research or diagnostic purposes).

187 Thus, our simulations reported in Appendix 2 suggest that reliability increases with number of  
 188 trials. However in some clinical populations, adding trials may not always be possible (e.g. when  
 189 patients cannot concentrate for a sufficiently long period of time), and might even be counterproduc-  
 190 tive (as strong fluctuations over time can induce extra noise). Our simulations reported in Appendix  
 191 3 show that for standard group-level comparisons, researchers can compensate for lower trial  
 192 numbers by increasing sample size. **Above all, we strongly encourage researchers to make in-  
 193 formed decisions about number of trials and participants, aiming for sufficiently-powered  
 194 studies.** The accompanying open-source simulation code can be used for this purpose.

#### 195 When and how to estimate SSRT

196 Recommendation 7: Do not estimate the SSRT when the assumptions of the race model  
 197 are violated

198 SSRTs can be estimated based on the independent race model, which assumes an independent  
 199 race between a go and a stop runner (Box 1). When this independence assumption is (seriously)  
 200 violated, SSRT estimates become unreliable (*Band et al., 2003*). Therefore, the assumption should  
 201 be checked. This can be done by comparing the mean RT on unsuccessful stop trials with the  
 202 mean RT on go trials. Note that this comparison should include all trials with a response (including  
 203 choice errors and premature responses), and it should be done for each participant and condition  
 204 separately. SSRT should not be estimated when RT on unsuccessful stop trials is numerically longer  
 205 than RT on go trials (see also, table 1 in Appendix 2). More formal and in-depth tests of the race  
 206 model can be performed (e.g. examining probability of responding and RT on unsuccessful stop  
 207 trials as a function of delay); however, a large number of stop trials is required for such tests to be  
 208 meaningful and reliable.

209 Recommendation 8: If using a non-parametric approach, estimate SSRT using the integra-  
 210 tion method (with replacement of go omissions)

211 Different SSRT estimation methods have been proposed (see Materials and Methods). When the  
 212 tracking procedure is used, the 'mean estimation' method is still the most popular (presumably  
 213 because it is very easy to use). However, the mean method is strongly influenced by the right tail  
 214 (skew) of the go RT distribution (see Appendix 2 for examples), as well as by go omissions (i.e. go  
 215 trials on which no response is executed). The simulations reported in Appendix 2 and summarized  
 216 in Figure 2 indicate that the integration method (which replaces go omissions with the maximum  
 217 RT in order to compensate for the lacking response) is generally less biased and more reliable than

<sup>3</sup>With 25% stop signals in an experiment, this amounts to 200 trials in total. Usually, this corresponds to an experiment of 7-10 minutes including breaks.

218 the mean method when combined with the tracking procedure. Unlike the mean method, the  
 219 integration method also does not assume that  $p(\text{respond} | \text{signal})$  is exactly .50 (an assumption that  
 220 is often not met in empirical data). Therefore, we recommend the use of the integration method  
 221 (with replacement of omissions on go trials) when non-parametric estimation methods are used.  
 222 We provide software and the source code for this estimation method (and all other recommended  
 223 measures; Recommendation 12).

224 Please note that some parametric SSRT estimation methods are less biased than even the best  
 225 non-parametric methods and avoid other problems that can beset them (see Box 2); however they  
 226 can be harder for less technically adept researchers to use, and they may require more trials (see  
 227 *Matzke et al., 2018*, for a discussion).

228 Recommendation 9: Refrain from estimating SSRT when the probability of responding on  
 229 stop-signal trials deviates substantially from .50 or when the probability of omissions on  
 230 go trials is high

231 Even though the preferred integration method (with replacement of go omissions) is less influenced  
 232 by deviations in  $p(\text{respond} | \text{signal})$  and go omissions than other methods, it is not completely  
 233 immune to them either (Figure 2 and Appendix 2). Previous work suggests that SSRT estimates  
 234 are most reliable (*Band et al., 2003*) when probability of responding on a stop trial is relatively  
 235 close to .50. Therefore, we recommend that researchers refrain from estimating individual SSRTs  
 236 when  $p(\text{respond} | \text{signal})$  is lower than .25 or higher than .75 (*Congdon et al., 2012*). Reliability of the  
 237 estimates is also influenced by go performance. As the probability of a go omission increases, SSRT  
 238 estimates also become less reliable. Figure 2 and the resources described in Appendix 3 can be  
 239 used to determine an acceptable level of go omissions at a study level. Importantly, researchers  
 240 should decide on these cut-offs or exclusion criteria before data collection has started.

## 266 **How to report stop-signal experiments**

267 Recommendation 10: Report the methods in enough detail

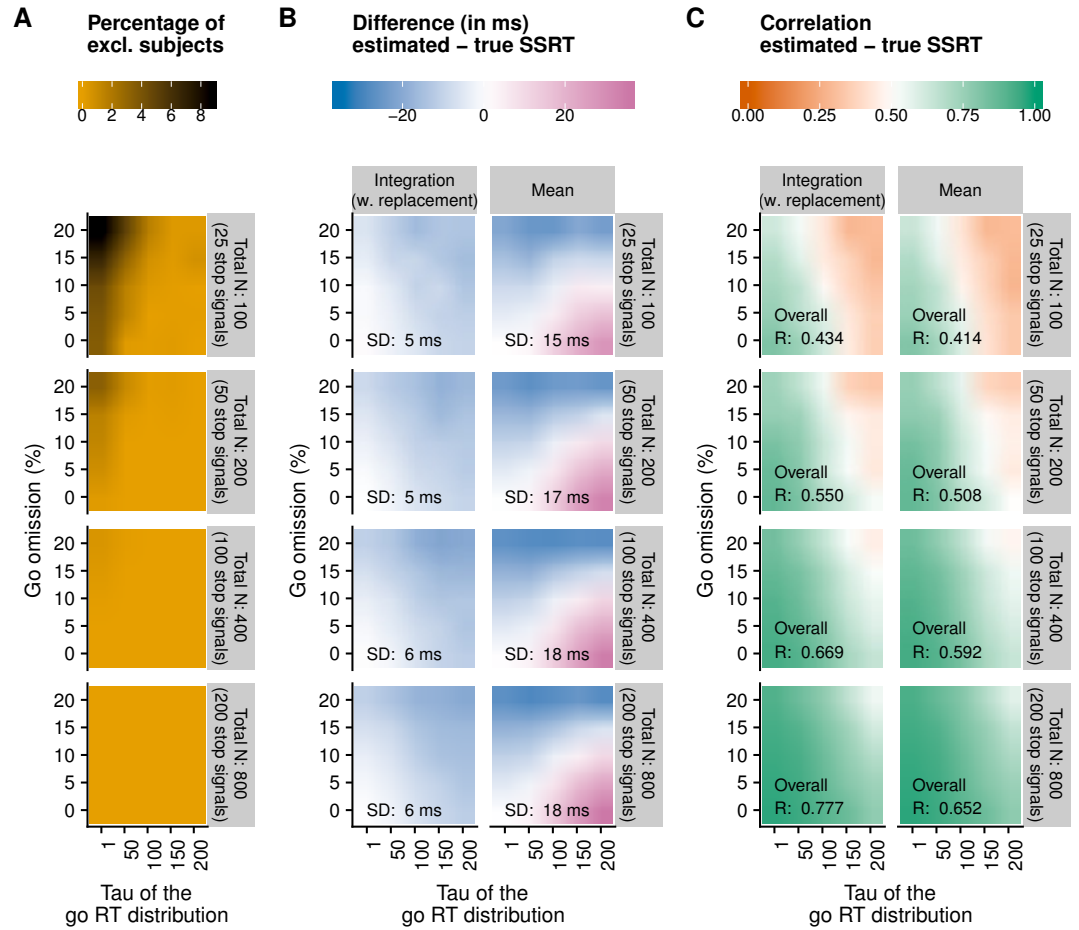

268 To allow proper evaluation and replication of the study findings, and to facilitate follow-up studies,  
 269 researchers should carefully describe the stimuli, materials, and procedures used in the study,  
 270 and provide a detailed overview of the performed analyses (including a precise description of how  
 271 SSRT was estimated). This information can be presented in Supplementary Materials in case of  
 272 journal restrictions. Box 3 provides a check-list that can be used by authors and reviewers. We also  
 273 encourage researchers to share their software and materials (e.g. the actual stimuli).

274 Recommendation 11: Report possible exclusions in enough detail

275 As outlined above, researchers should refrain from estimating SSRT when the independence  
 276 assumptions are seriously violated or when sub-optimal task performance might otherwise com-  
 277 promise the reliability of the estimates. The number of participants for whom SSRT was not  
 278 estimated should be clearly mentioned. Ideally, dependent variables which are directly observed  
 279 (see Recommendation 12) are separately reported for the participants that are not included in the  
 280 SSRT analyses. Researchers should also clearly mention any other exclusion criteria (e.g. outliers  
 281 based on distributional analyses, acceptable levels of go omissions, etc.), and whether those were  
 282 set a-priori (analytic plans can be preregistered on a public repository, such as the [Open Science](#)  
 283 [Framework](#); *Nosek et al., 2018*).

284 Recommendation 12: Report all relevant behavioral data

285 Researchers should report all relevant descriptive statistics that are required to evaluate the findings  
 286 of their stop-signal study (see Box 3 for a check-list). These should be reported for each group or  
 287 condition separately. As noted above (Recommendation 7), additional checks of the independent  
 288 race model can be reported when the number of stop-signal trials is sufficiently high. Finally,

**Figure 2.** Main results of the simulations reported in Appendix 2. Here we show a comparison of the integration method (with replacement of go omissions) and the mean method, as a function of percentage of go omissions, skew of the RT distribution ( $\tau_{go}$ ), and number of trials. Appendix 2 provides a full overview of all methods. **A:** The number of excluded ‘participants’ (RT on unsuccessful stop trials > RT on go trials). As this check was performed before SSRTs were estimated (see Recommendation 7), the number was the same for both estimation methods. **B:** The average difference between the estimated and true SSRT (positive values = overestimation; negative values = underestimation). SD = standard deviation of the difference scores (per panel). **C:** Correlation between the estimated and true SSRT (higher values = more reliable estimate). Overall R = correlation when collapsed across percentage of go omissions and  $\tau_{go}$ . (Please note that the overall correlation does not necessarily correspond to the average of individual correlations.)

**242 Box 2. Failures to trigger the stop process**

243 The race model assumes that the go runner is triggered by the presentation of the go stimulus,  
244 and the stop runner by the presentation of the stop signal. However, go omissions (i.e. go trials  
245 without a response) are often observed in stop-signal studies. Our preferred SSRT method  
246 compensates for such go omissions (see Materials and Methods). However, turning to the  
247 stopping process, studies using fixed SSDs have found that  $p(\text{respond} | \text{signal})$  at very short  
248 delays (including  $\text{SSD} = 0$  ms, when go and stop are presented together) is not always zero;  
249 this finding indicates that the stop runner may also not be triggered on all stop trials ('trigger  
250 failures').

251 The non-parametric estimation methods described in Materials and Methods (see also Ap-  
252 pendix 2) will overestimate SSRT when trigger failures are present on stop trials (**Band et al.,**  
253 **2003**). Unfortunately, these estimation methods cannot determine the presence or absence  
254 of trigger failures on stop trials. In order to diagnose in how far trigger failures are present  
255 in their data, researchers can include extra stop signals that occur at the same time of the  
256 go stimulus (i.e.  $\text{SSD} = 0$ , or shortly thereafter). Note that this number of zero-SSD trials  
257 should be sufficiently high to detect (subtle) within- or between-group differences in trigger  
258 failures. Furthermore,  $p(\text{respond} | \text{signal})$  should be reported separately for these short-SSD  
259 trials, and these trials should not be included when calculating mean SSD or estimating SSRT  
260 (see Recommendation 1 for a discussion of problems that arise when SSDs are very short).  
261 Alternatively, researchers can use a parametric method to estimate SSRT. Such methods de-  
262 scribe the whole SSRT distribution (unlike the non-parametric methods that estimate summary  
263 measures, such as the mean stop latency). Recent variants of such parametric methods also  
264 provide an estimate of the probability of trigger failures on stop trials (for the most recent  
265 version and specialized software, see **Matzke et al., 2019**).

289 we encourage researchers to share their anonymized raw (single-trial) data when possible (in  
290 accordance with the FAIR data guidelines; *Wilkinson et al., 2016*).

### 332 **Conclusion**

333 Response inhibition and impulse control are central topics in various fields of research, including  
334 neuroscience, psychiatry, psychology, neurology, pharmacology, and behavioral sciences, and the  
335 stop-signal task has become an essential tool in their study. If properly used, the task can reveal  
336 unique information about the underlying neuro-cognitive control mechanisms. By providing clear  
337 recommendations, and open-source resources, this paper aims to further increase the quality of  
338 research in the response-inhibition and impulse-control domain and significantly accelerate its  
339 progress across the various important domains in which it is routinely applied.

### 340 **Materials and Methods**

341 The independent race model (Box 1) provides two common 'non-parametric' methods for estimating  
342 SSRT: the integration method and the mean method. Both methods have been used in slightly  
343 different flavors in combination with the SSD tracking procedure (see Recommendation 4). Here we  
344 discuss the two most typical estimation variants, which we further scrutinized in our simulations  
345 (Appendix 2). We refer the reader to Appendix 2 and 3 for a detailed description of the simulations.

#### 346 **Integration method (with replacement of go omissions)**

347 In the integration method, the point at which the stop process finishes (Box 1) is estimated by  
348 'integrating' the RT distribution and finding the point at which the integral equals  $p(\text{respond} | \text{signal})$ .  
349 The finishing time of the stop process corresponds to the  $n$ th RT, with  $n$  = the number of RTs in  
350 the RT distribution of go trials multiplied by  $p(\text{respond} | \text{signal})$ . When combined with the tracking  
351 procedure, overall  $p(\text{respond} | \text{signal})$  is used. For example, when there are 200 go trials, and overall  
352  $p(\text{respond} | \text{signal})$  is .45, then the  $n$ th RT is the 90th fastest go RT. SSRT can then be estimated by  
353 subtracting mean SSD from the  $n$ th RT. To determine the  $n$ th RT, all go trials with a response are  
354 included (*including go trials with a choice error and go trials with a premature response*). Importantly, go  
355 omissions (i.e. go trials on which the participant did not respond before the response deadline) are  
356 assigned the maximum RT in order to compensate for the lacking response. Premature responses  
357 on unsuccessful stop trials (i.e. responses executed before the stop signal is presented) should also  
358 be included when calculating  $p(\text{respond} | \text{signal})$  and mean SSD (as noted in Recommendation 4,  
359 SSD should also be adjusted after such trials). **This version of the integration method produces  
360 the most reliable and least biased (non-parametric) SSRT estimates (Appendix 2).**

#### 361 **The mean method**

362 The mean method uses the mean of the inhibition function (which describes the relationship  
363 between  $p(\text{respond} | \text{signal})$  and SSD). Ideally, this mean corresponds to the average SSD obtained  
364 with the tracking procedure when  $p(\text{respond} | \text{signal}) = .50$  (and often this is taken as a given despite  
365 some variation). In other words, the mean method assumes that the mean RT equals SSRT + mean  
366 SSD, so SSRT can be estimated easily by subtracting mean SSD from mean RT on go trials when the  
367 tracking procedure is used. The ease of use has made this the most popular estimation method.  
368 **However, our simulations show that this simple version of the mean method is biased and  
369 generally less reliable than the integration method with replacement of go omissions.**

372 Horizon 2020 research and innovation programme, grant agreement No 769595).

### 292 **Box 3. Check-lists for reporting stop-signal studies**

293 The description of every stop-signal study should include the following information:

- 294 • Stimuli and materials
  - 295 – Properties of the go stimuli, responses, and their mapping
  - 296 – Properties of the stop signal
  - 297 – Equipment used for testing
- 298 • The procedure
  - 299 – The number of blocks (including practice blocks)
  - 300 – The number of go and stop trials per block
  - 301 – Detailed description of the randomization (e.g. is the order of go and stop trials fully
  - 302 randomized or pseudo-randomized?)
  - 303 – Detailed description of the tracking procedure (including start value, step size,
  - 304 minimum and maximum value) or the range and proportion of fixed stop-signal
  - 305 delays.
  - 306 – Timing of all events. This can include intertrial intervals, fixation intervals (if applica-
  - 307 ble), stimulus-presentation times, maximum response latency (and whether a trial is
  - 308 aborted when a response is executed or not), feedback duration (in case immediate
  - 309 feedback is presented), etc.
  - 310 – A summary of the instructions given to the participant, and any feedback-related
  - 311 information (full instructions can be reported in Supplementary Materials).
  - 312 – Information about training procedures (e.g. in case of animal studies)
- 313 • The analyses
  - 314 – Which trials were included when analyzing go and stop performance
  - 315 – Which SSRT estimation method was used (see Materials and Methods), providing
  - 316 additional details on the exact approach (e.g. whether or not go omissions were
  - 317 replaced; how go and stop trials with a choice errors–e.g. left response for right
  - 318 arrows–were handled; how the nth quantile was estimated; etc.)
  - 319 – Which statistical tests were used for inferential statistics

320 Stop-signal studies should also report the following descriptive statistics for each group and  
321 condition separately (see Appendix 4 for a description of all labels):

- 322 • Probability of go omissions (no response)
- 323 • Probability of choice errors on go trials
- 324 • RT on go trials (mean or median). We recommend to report intra-subject variability as
- 325 well (especially for clinical studies).
- 326 • Probability of responding on a stop-signal trial (for each SSD when fixed delays are used)
- 327 • Average stop-signal delay (when the tracking procedure is used); depending on the set-up,
- 328 it is advisable to report (and use) the 'real' SSDs (e.g. for visual stimuli, the requested SSD
- 329 may not always correspond to the real SSD due to screen constraints).
- 330 • Stop-signal reaction time
- 331 • RT of go responses on unsuccessful stop trials

## 432 Appendix 2

433 **Race model simulations to determine estimation bias and reliability**  
434 **of SSRT estimates**435 **Simulation procedure**

436 To compare different SSRT estimation methods, we ran a set of simulations which simulated  
437 performance in the stop-signal task based on assumptions of the independent race model:  
438 on stop-signal trials, a response was deemed to be stopped (successful stop) when the RT  
439 was larger than SSRT + SSD; a response was deemed to be executed (unsuccessful stop)  
440 when RT was smaller than SSRT + SSD. Go and stop were completely independent.

441 All simulations were done using R (R Core Team, 2019). Latencies of the go and stop runners  
442 were sampled from an ex-Gaussian distribution, using the `rexGaus` function (R Core Team, 2019,  
443 5.1.2). The ex-Gaussian distribution has a positively skewed unimodal shape and results  
444 from a convolution of a normal (Gaussian) distribution and an exponential distribution. It is  
445 characterized by three parameters:  $\mu$  (mean of the Gaussian component),  $\sigma$  (SD of Gaussian  
446 component), and  $\tau$  (both the mean and SD of the exponential component). The mean of the  
447 ex-Gaussian distribution =  $\mu + \tau$ , and variance =  $\sigma^2 + \tau^2$ . Previous simulation studies of the  
448 stop-signal task also used ex-Gaussian distributions to model their reaction times (e.g. *Band*  
449 *et al., 2003; Verbruggen et al., 2013; Matzke et al., 2019*).

450 For each simulated 'participant',  $\mu_{go}$  of the ex-Gaussian go RT distribution was sampled  
451 from a normal distribution with mean = 500 (i.e. the population mean) and SD = 50, with the  
452 restriction that it was larger than 300 (see *Verbruggen et al., 2013*, for a similar procedure).  
453  $\sigma_{go}$  was fixed at 50, and  $\tau_{go}$  was either 1, 50, 100, 150, and 200 (resulting in increasingly  
454 skewed distributions). The RT cut-off was set at 1,500 ms. Thus, go trials with an RT >  
455 1,500 ms were considered go omissions. For some simulations, we also inserted extra go  
456 omissions, resulting in five 'go omission' conditions: 0% inserted go omissions (although the  
457 occasional go omission was still possible when  $\tau_{go}$  was high), 5%, 10%, 15%, or 20%. These  
458 go omissions were randomly distributed across go and stop trials. For the 5%, 10%, 15%,  
459 and 20% go-omission conditions, we checked first if there were already go omissions due  
460 to the random sampling from the ex-Gaussian distribution. If such go omissions occurred  
461 'naturally', fewer 'artificial' omissions were inserted.

462  
463 **Appendix 2 Figure 1.** Examples of ex-Gaussian (RT) distributions used in our simulations. For all  
464 distributions,  $\mu_{go} = 500$  ms, and  $\sigma_{go} = 50$  ms.  $\tau_{go}$  was either 1, 50, 100, 150, and 200 (resulting in  
465 increasingly skewed distributions). Note that for a given RT cut-off (1500 ms in the simulations),  
466 cut-off-related omissions are rare, but systematically more likely as tau increases. In addition to such  
467 'natural' go omissions, we introduced 'artificial' ones in the different go-omission conditions of the  
468 simulations (not depicted).

For each simulated 'participant',  $\mu_{stop}$  of the ex-Gaussian SSRT distribution was sampled  
from a normal distribution with mean = 200 (i.e. the population mean) and SD = 20, with the

470

471

472

473

474

475

restriction that it was larger than 100.  $\sigma_{stop}$  and  $\tau_{stop}$  were fixed at 20 and 10, respectively. For each 'participant', the start value of SSD was 300 ms, and was continuously adjusted using a standard tracking procedure (see main text) in steps of 50 ms. In the present simulations, we did not set a minimum or maximum SSD.

476

477

478

479

480

481

The total number of trials simulated per participant was either 100, 200, 400, or 800, whereas the probability of a stop-signal was fixed at .25; thus, the number of stop trials was 25, 50, 100, or 200, respectively. This resulted in 5 (go omission: 0, 5, 10, 15, or 20%) x 5 ( $\tau_{go}$ : 1, 50, 100, 150, 200) x 4 (total number of trials: 100, 200, 400, 800) conditions. For each condition, we simulated 1000 participants. Overall, this resulted in 100,000 participants (and 375,000,000 trials).

482

## Analyses

We performed three sets of analyses. First, we checked if RT on unsuccessful stop trials was numerically shorter than RT on go trials. Second, we estimated SSRTs using the two estimation methods described in the main manuscript (Materials and Methods), and two other methods that have been used in the stop-signal literature. The first additional approach is a variant of the integration method described in the main manuscript. The main difference is the exclusion of go omissions (and sometimes choice errors on unsuccessful stop trials) from the go RT distribution when determining the nth RT. The second additional variant also does not assign go omissions the maximum RT. Rather, this method adjusts  $p(\text{respond} | \text{signal})$  to compensate for go omissions (?):

495

496

$$p(\text{respond} | \text{signal})_{\text{adjusted}} = 1 - \frac{p(\text{inhibit} | \text{signal}) - p(\text{omission} | \text{go})}{1 - p(\text{omission} | \text{go})}$$

497

498

499

500

501

502

503

504

505

506

The nth RT is then determined using the adjusted  $p(\text{respond} | \text{signal})$  and the distribution of RTs of all go trials with a response.

Thus, we estimated SSRT using four different methods: (1) integration method with replacement of go omissions; (2) integration method with exclusion of go omissions; (3) integration method with adjustment of  $p(\text{respond} | \text{signal})$ ; and (4) the mean method. For each estimation method and condition (go omission x  $\tau_{go}$  x number of trials), we calculated the difference between the estimated SSRT and the actual SSRT; positive values indicate that SSRT is overestimated, whereas negative values indicate that SSRT is underestimated. For each estimation method, we also correlated the true and estimated values across participants; higher values indicate more reliable SSRT estimates.

507

508

509

510

511

512

We investigated all four mentioned estimation approaches in the present appendix. In the main manuscript, we provide a detailed overview focussing on (1) the integration method with replacement of go omissions and (2) the mean method. As described below, the integration method with replacement of go omissions was the least biased and most reliable, but we also show the mean method in the main manuscript to further highlight the issues that arise when this (still popular) method is used.

513

## Results

All figures were produced using the ggplot2 package (version 3.1.0 ?). The number of excluded 'participants' (i.e. RT on unsuccessful stop trials > RT on go trials) is presented in Figure 2 of the main manuscript. Note that these are only apparent violations of the independent race model, as go and stop were always modelled as independent runners. Instead, the longer RTs on unsuccessful stop trials result from estimation uncertainty associated with estimating mean RTs using scarce data. However, as true SSRT of all participants was known,

we could nevertheless compare the SSRT bias for included and excluded participants. As can be seen in the table below, estimates were generally much more biased for 'excluded' participants than for 'included' participants. Again this indicates that **extreme data are more likely to occur when the number of trials is low**.

Estimation method	Included	Excluded
Integration with replacement of go omissions	-6.4	-35.8
Integration without replacement of go omissions	-19.4	-48.5
Integration with adjusted $p(\text{respond}   \text{signal})$	12.5	-17.4
Mean	-16.0	-46.34

**Appendix 2 Table 1.** The mean difference between estimated and true SSRT for participants who were included in the main analyses and participants who were excluded (because average RT on unsuccessful stop trials > average RT on go trials). We did this only for  $\tau_{go} = 1$  or 50,  $p(\text{go omission}) = 10, 15, \text{ or } 20$ , and number of trials = 100 (i.e. when the number of excluded participants was high; see Panel A, Figure 2 of the main manuscript).

To further compare differences between estimated and true SSRTs for the included participants, we used 'violin plots'. These plots show the distribution and density of SSRT difference values. We created separate plots as a function of the total number of trials (100, 200, 400, and 800), and each plot shows the SSRT difference as a function of estimation method, percentage of go omissions, and  $\tau_{go}$  (i.e. the skew of the RT distribution on go trials; see Appendix 2 Figure ??). The plots can be found below. The first important thing to note is that the scales differ between subplots. This was done intentionally, as the distribution of difference scores was wider when the number of trials was lower (with fixed scales, it is difficult to detect meaningful differences between estimation methods and conditions for higher trial numbers; i.e. Panels C and D). In other words, **low trial numbers will produce more variable and less reliable SSRT estimates**.

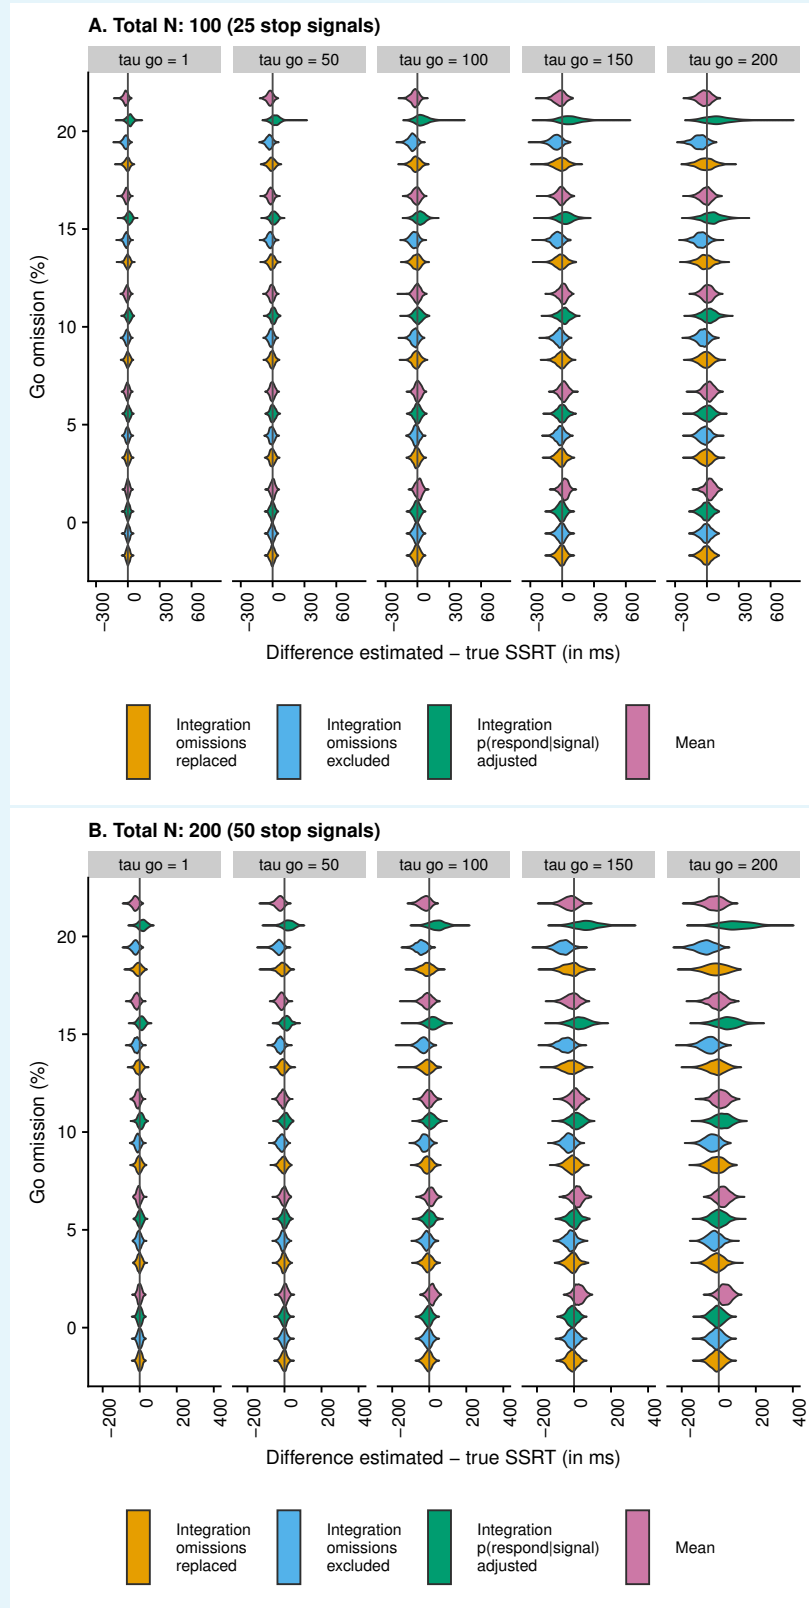

Second, the violin plots show that **SSRT estimates are strongly influenced by an increasing percentage of go omissions**. The figures show that the integration method with replacement of go omissions, integration method with exclusion of go omissions, and the mean method all have a tendency to underestimate SSRT as the percentage of go omissions increases; importantly, *this underestimation bias is most pronounced for the integration method with exclusion of go omissions*. By contrast, the integration method which uses the adjusted  $p(\text{respond} | \text{signal})$  will overestimate SSRT when go omissions are present; compared with the other methods, this bias was the strongest in absolute terms.

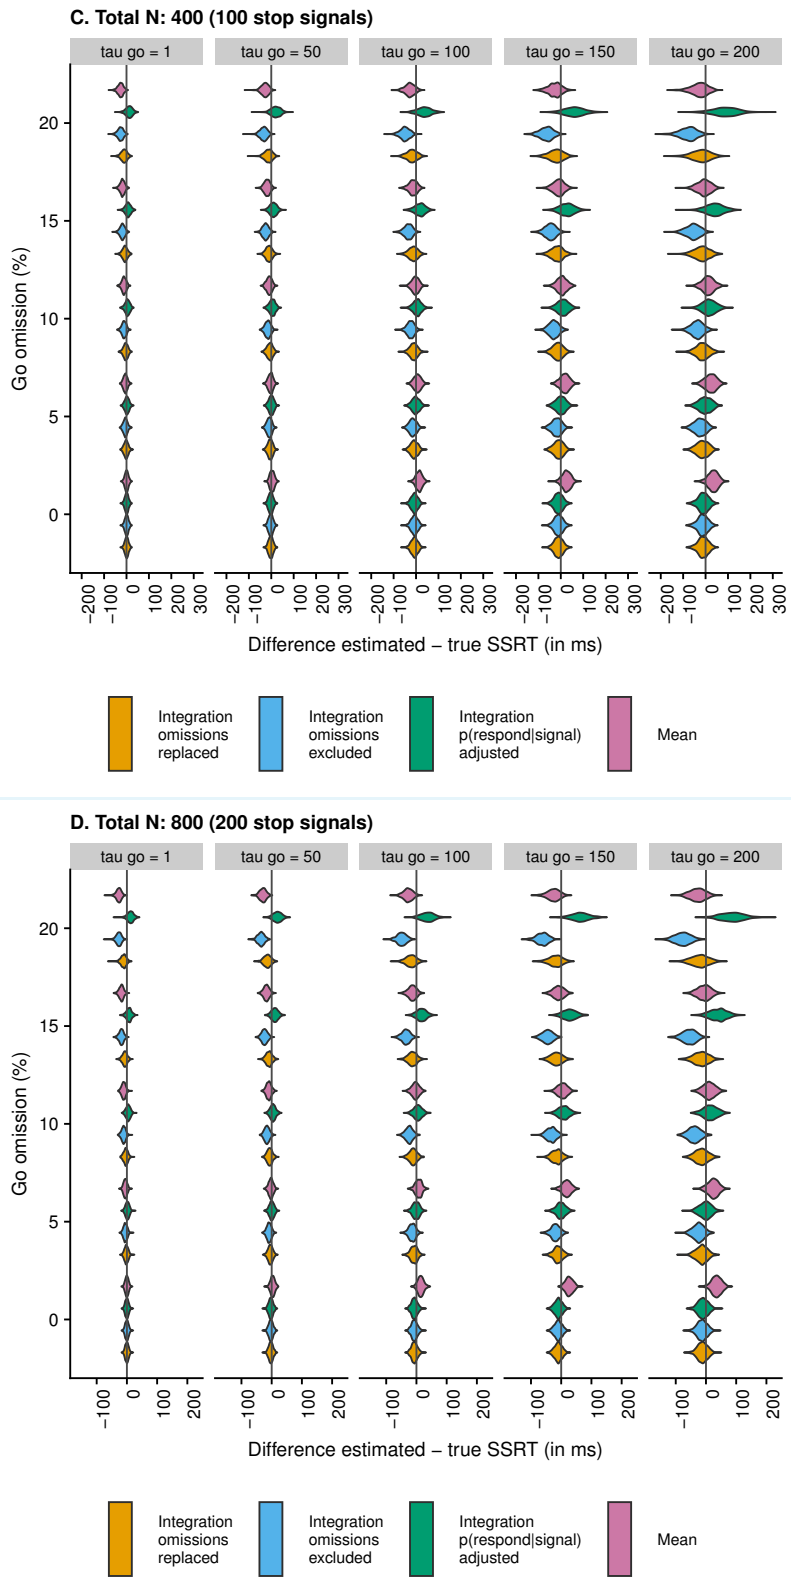

Consistent with previous work (*Verbruggen et al., 2013*), **skew of the RT distribution also strongly influenced the estimates**. SSRT estimates were generally more variable as  $\tau_{go}$  increased. When the probability of a go omission was low, the integration methods showed a small underestimation bias for high levels of  $\tau_{go}$ , whereas the mean method showed a clear overestimation bias for high levels of  $\tau_{go}$ . In absolute terms, this overestimation bias for the mean method was more pronounced than the underestimation bias for the integration methods. For higher levels of go omissions, the pattern became more complicated as the various biases started to interact. Therefore, we also correlated the true SSRT with the estimated SSRT to compare the different estimation methods.

To calculate the correlation between true and estimated SSRT for each method, we collapsed across all combinations of  $\tau_{go}$ , go omission rate, and number of trials. **The correlation (i.e. reliability of the estimate) was highest for the integration method with replacement of go omissions,  $r = .57$**  (as shown in the violin plots, this was also the least biased method); intermediate for the mean method,  $r = .53$ , and the integration method

560  
561  
562  
563  
564  
565

with exclusion of go errors,  $r = .51$ ; and lowest for the integration method using adjusted  $p(\text{respond}|\text{signal})$ ,  $r = .43$ .

566  
567  
568  
569

570 **Appendix 2 Figure 2.** Violin plots showing the distribution and density of the difference scores  
571 between estimated and true SSRT as a function of condition and estimation method. Values smaller  
572 than zero indicate underestimation; values larger than zero indicate overestimation.

574 **Appendix 3**575 **Race model simulations to determine achieved power**576 **Simulation procedure**

577 To determine how different parameters affected the power to detect SSRT differences, we  
 578 simulated 'experiments'. We used the same general procedure as described in Appendix 2.  
 579 In the example described below, we used a simple between-groups design with a control  
 580 group and an experimental group.

581 For each simulated 'participant' of the 'control group',  $\mu_{go}$  of the ex-Gaussian go RT  
 582 distribution was sampled from a normal distribution with mean = 500 (i.e. the population  
 583 mean) and SD = 100, with the restriction that it was larger than 300.  $\sigma_{go}$  and  $\tau_{go}$  were both  
 584 fixed at 50, and the percentage of (artificially inserted) go omissions was 0% (see Appendix  
 585 2).  $\mu_{stop}$  of the ex-Gaussian SSRT distribution was also sampled from a normal distribution  
 586 with mean = 200 (i.e. the population mean) and SD = 40, with the restriction that it was  
 587 larger than 100.  $\sigma_{stop}$  and  $\tau_{stop}$  were fixed at 20 and 10, respectively. Please note that the SDs  
 588 for the population means were higher than the values used for the simulations reported in  
 589 Appendix 2 to allow for extra between-subjects variation in our groups.

590 For the 'experimental group', the go and stop parameters could vary across 'experiments'.  
 591  $\mu_{go}$  was sampled from a normal distribution with population mean = 500, 525, or 575 (SD =  
 592 100).  $\sigma_{go}$  was 50, 52.5, or 57.5 (for population mean of  $\mu_{go}$  = 500, 525, and 575, respectively),  
 593 and  $\tau_{go}$  was either 50, 75, or 125 (also for population mean of  $\mu_{go}$  = 500, 525, and 575,  
 594 respectively). Remember that the mean of the ex-Gaussian distribution =  $\mu + \tau$  (Appendix 2).  
 595 Thus, mean go RT of the experimental group was either 550 ms (500 + 50, which is the same  
 596 as the control group), 600 (525+75), or 700 (575 + 125). The percentage of go omissions for  
 597 the experimental group was either 0% (the same as the experimental group), 5% (for  $\mu_{go}$  =  
 598 525) or 10% (for  $\mu_{go}$  = 575).

Parameters of go distribution	Control	Experimental 1	Experimental 2	Experimental 3
$\mu_{go}$	500	500	525	575
$\sigma_{go}$	50	50	52.5	57.5
$\tau_{go}$	50	50	75	125
go omission	0	0	5	10

599 **Table 1.** Parameters of the go distribution for the control group and the three experimental conditions.  
 602 SSRT of all experimental groups differed from SSRT in the control group (see below)

604  $\mu_{stop}$  of the 'experimental-group' SSRT distribution was sampled from a normal distribution  
 605 with mean = 210 or 215 (SD = 40).  $\sigma_{stop}$  was 21 or 21.5 (for  $\mu_{stop}$  = 210 and 215, respectively),  
 606 and  $\tau_{stop}$  was either 15 (for population mean of  $\mu_{stop}$  = 210) or 20 (for population mean of  
 607  $\mu_{stop}$  = 215). Thus, mean SSRT of the experimental group was either 225 ms (210 + 15,  
 608 corresponding to a medium effect size; Cohen's  $d \approx .50$ -55. Note that the exact value  
 609 could differ slightly between simulations as random samples were taken) or 235 (215 + 20,  
 610 corresponding to a large effect size; Cohen's  $d \approx .85$ -90). SSRT varied independently from  
 611 the go parameters (i.e.  $\mu_{go} + \tau_{go}$ , and % go omissions).

The total number of trials per experiment was either 100 (25 stop trials), 200 (50 stop trials) or 400 (100 stop trials). Other simulation parameters were the same as those described in Appendix 2. Overall, this resulted in 18 different combinations: 3 (go difference between control and experimental; see Table 1 above) x 2 (mean SSRT difference between control

and experimental: 15 or 30) x 3 (total number of trials: 100, 200 or 400). For each parameter combination, we simulated 5000 'pairs' of subjects.

The code and results of the simulations are available via the Open Science Framework (<https://osf.io/rmqaw/>); stop-signal users can adjust the scripts (e.g. by changing parameters or even the design) to determine the required sample size given some consideration about the expected results. Importantly, the present simulation code provides access to a wide set of parameters (i.e. go omission, parameters of the go distribution, and parameters of the SSRT distribution) that could differ across groups or conditions.

## Analyses

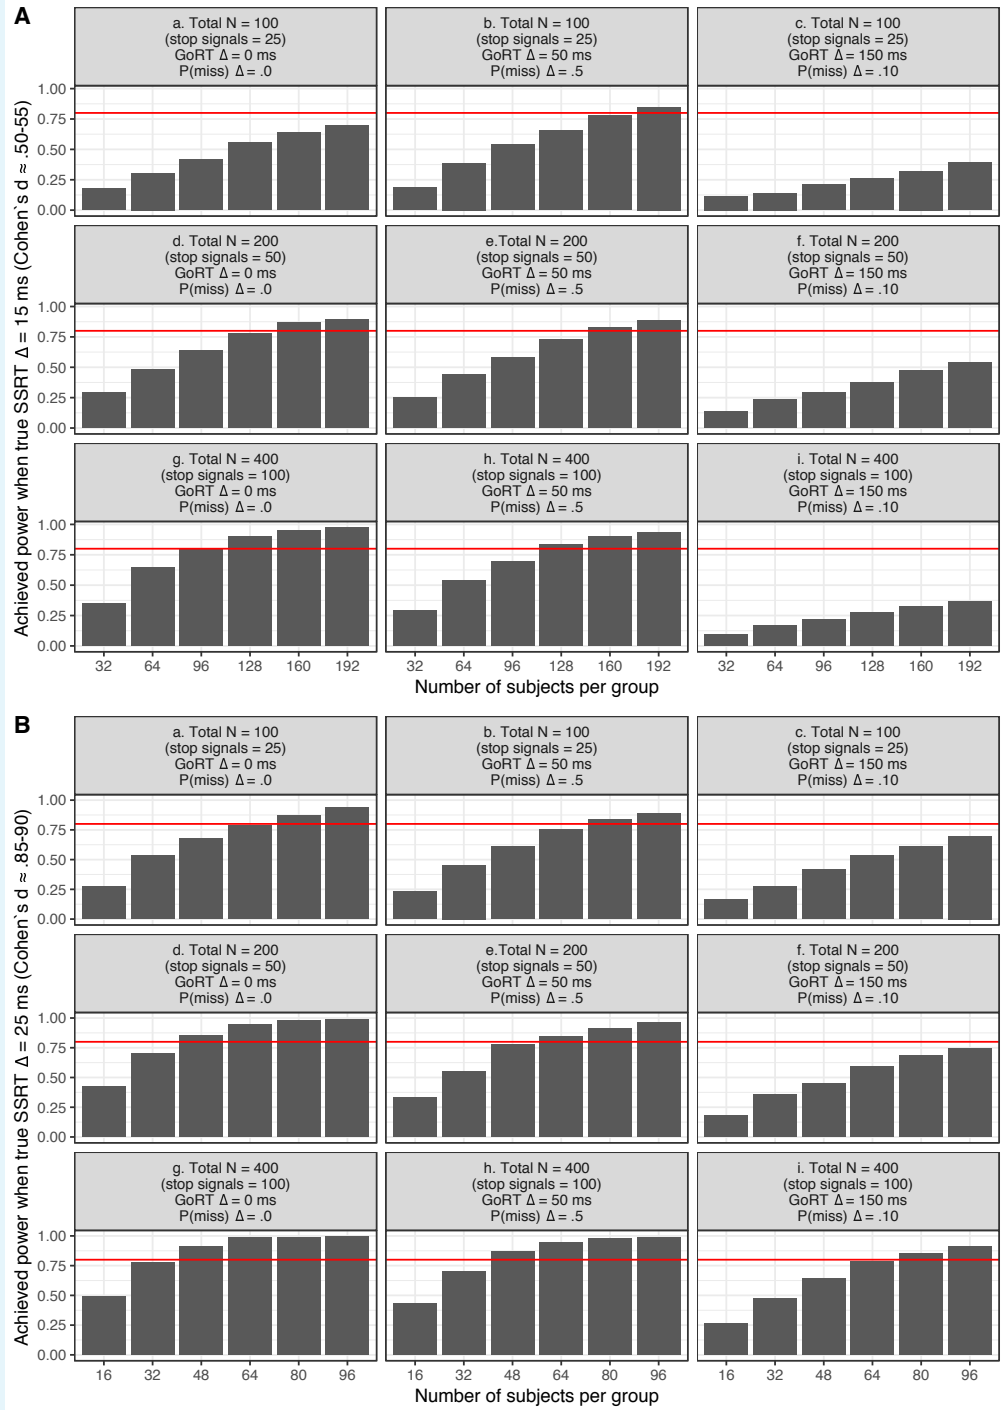

SSRTs were estimated using the integration method with replacement of go omissions (i.e. the method that came out on top in the other set of simulations). Once the SSRTs were estimated, we randomly sampled 'pairs' to create the two groups for each 'experiment'. For the 'medium' SSRT difference (i.e. 210 vs. 225 ms), group size was either 32, 64, 96, 128, 160, or 192 (the total number of participants per experiment was twice the group size). For the 'large' SSRT difference (i.e. 210 vs. 235 ms), group size was either 16, 32, 48, 64, 80, or 96 (the total number of participants per experiment was twice the group size). For each sample size and parameter combination (see above), we repeated this procedure 1,000 times (or 1,000 experiments).

For each experiment, we subsequently compared the estimated SSRTs of the control and experiment groups with an independent-samples t-test (assuming unequal variances). Then we determined for each sample size x parameter combination the proportion of t-tests that were significant (with  $\alpha = .05$ ).

## Results

The figure below plots achieved power as a function of sample size (per group), experimental vs. control group difference in true SSRT, and group differences in go performance. Note that if true and estimated SSRTs would exactly match (i.e. estimations reliability = 1), approximately 58 participants per group would be required to detect a medium-sized true SSRT difference with power = .80 (i.e. when Cohen's  $d \approx .525$ ), and 22 participants per group for a large-sized true SSRT difference (Cohen's  $d \approx .875$ ).

Inspection of the figure clearly reveals that achieved power generally increases when sample size and number of trials increase. Obviously achieved power is also strongly dependent on effect size (Panel A vs. B). Interestingly, the figure also shows that the ability to detect SSRT differences is reduced when go performance of the groups differ substantially (see second and third columns of Panel A). As noted in the main manuscript and Appendix 2, even the integration method (with replacement of go omissions) is not immune to changes in the go performance. More specifically, SSRT will be underestimated when the RT distribution is skewed (note that all other approaches produce an even stronger bias). In this example, the underestimation bias will reduce the observed SSRT difference (as the underestimation bias is stronger for the experimental group than for the control group). Again, this highlights the need to encourage consistent fast responding (reducing the right-end tail of the distribution).

661

**Overview of the main labels and common alternatives**

Label	Description	Common alternative labels
Stop-signal task	A task used to measure response inhibition in the lab. Consists of a go component (e.g. a two-choice discrimination task) and a stop component (suppressing the response when an extra signal appears).	Stop-signal reaction time task, stop-signal paradigm, countermanding task
Go trial	On these trials (usually the majority), participants respond to the go stimulus as quickly and accurately as possible (e.g. left arrow = left key, right arrow = right key).	No-signal trial, no-stop-signal trial
Stop trial	On these trials (usually the minority), an extra signal is presented after a variable delay, instructing participants to stop their response to the go stimulus.	Stop-signal trial, signal trial
Successful stop trial	On these stop trials, the participants successfully stopped (inhibited) their go response.	Stop-success trial, signal-inhibit trial, canceled trial
Unsuccessful stop trial	On these stop-signal trials, the participants could not inhibit their go response; hence, they responded despite the (stop-signal) instruction not to do so.	Stop-failure trial, signal-respond trial, noncanceled trial, stop error

662

663

<b>Label</b>	<b>Description</b>	<b>Common alternative labels</b>
Go omission	Go trials without a go response.	Go-omission error, misses, missed responses
Choice errors on go trials	Incorrect response on a go trial (e.g. the go stimulus required a left response but a right response was executed).	(Go) errors, incorrect (go or no-signal) trials
Premature response on a go trial	A response executed before the presentation of the go stimulus on a go trial. This can happen when go-stimulus presentation is highly predictable in time (and stimulus identity is not relevant to the go task; e.g. in a simple detection task) or when participants are 'impulsive'. Note that response latencies will be negative on such trials.	

Label	Description	Common alternative labels
P(respond signal)	Probability of responding on a stop trial. Non-parametric estimation methods (Materials and Methods) use p(respond signal) to determine SSRT.	P(respond), response rate, $p(\text{inhibit}) = 1 - p(\text{respond}   \text{signal})$
Choice errors on unsuccessful stop trials	Unsuccessful stop trials on which the incorrect go response was executed (e.g. the go stimulus required a left response but a right response was executed).	Incorrect signal-respond trials
Premature responses on unsuccessful stop trials	This is a special case of unsuccessful stop trials, referring to responses executed before the presentation of the go stimulus on stop trials (see description premature responses on go trials). In some studies, this label is also used for go responses executed <i>after</i> the presentation of the go stimulus but <i>before</i> the presentation of the stop signal.	Premature signal-respond
Trigger failures on stop trials	Failures to launch the stop process or 'runner' on stop trials (see Box 2 for further discussion).	

664

665

666

Note: The different types of unsuccessful stop trials are usually collapsed when calculating p(respond|signal), estimating SSRT, or tracking SSD.

667

<b>Label</b>	<b>Description</b>	<b>Common alternative labels</b>
Reaction time (RT) on go trials	How long does it take to respond to the stimulus on go trials? This corresponds to the finishing time of the go runner in the independent race model.	Go RT, go latency, no-signal RT
Stop-signal delay (SSD)	The delay between the presentation of the go stimulus and the stop-signal	Stimulus-onset asynchrony (SOA)
Stop-signal reaction time (SSRT)	How long does it take to stop a response? SSD + SSRT correspond to the finishing time of the stop runner in the independent race model.	Stop latency
RT on unsuccessful stop trials	Reaction time of the go response on unsuccessful stop trials	Signal-respond RT, SR-RT (note that this abbreviation is highly similar to the abbreviation for stop-signal reaction time, which can cause confusion)
