Supporting Information

ABSTRACT: Many polyols are abundant and cheap molecules highly spread in the biomass. These molecules have an enormous potential to be used in electrochemical devices to generate energy and/or value-added molecules. The electrooxidation of polyols can produce different substances of interest in the chemical industry concomitantly to high purity hydrogen in electrolyzers. The cost in the production of all these chemicals depends, among other factors, on the develop of more active and selective catalysts. However, in order to search for these materials using computational experiments, it is mandatory to have a better understanding of the fundamental aspect of the reactions, which permit to base the search on the adsorption energies of one or more key reaction intermediates. To contribute to this task, we performed (spectro)-electrochemical and computational experiments to study the electrooxidation of C₄ polyols. We show that the electrooxidation of polyols does not depend on the relative orientation of their OH groups. Besides, using Pt single crystals, we demonstrate that the trend for the oxidation of the primary carbon (relative to the secondary) increases in the order Pt(111) < Pt(100) < Pt(110) and that this result can be extended to polyols with longer carbon chains. Finally, computational experiments permit us to rationalize these trends looking at the relative stability of double dehydrogenated intermediates on the Pt basal planes.

INTRODUCTION

Increasing concerns about climate change and pollution are pushing the chemical industry to adopt greener strategies in their industrial processes. This scenario is creating significant opportunities for biobased economies.¹ Hence, several biofuels are attractive candidates to be used in fuel cells (to produce energy and value-added compounds) and in electrolyzers (to produce value added products).^{2–6}

In this context, the electrooxidation of polyols (EOP) has been studied extensively on platinum electrodes in acid media. These reactions share several similarities, irrespective of the exact molecule: (1) If the reaction occurs mainly without C–C bond breaking, it is selective to the oxidation of the primary carbon, producing a highly reactive aldehyde that easily reacts to form the corresponding acid.^{7–11} (2) If the C–C bond breaks, adsorbed CO is formed, which poisons the electrode.^{12–18} (3) CO is not the only adsorbed reaction intermediate; there exist other species that strongly adsorb on the electrode, though their exact nature has remained elusive.¹⁹

Glycerol (GLOH) is the most studied molecule for the EOP as it is the simplest structure containing a primary and a secondary carbon. Garcia et al.¹⁹ gave atomic-level insight about the selectivity of GLOH oxidation on Pt(111) and Pt(100) single crystal electrodes in terms of the oxidation of

the primary or secondary alcohol. They found different selectivity on the two surfaces: only primary alcohol oxidation on Pt(100) and both primary and secondary alcohol oxidation on Pt(111). They related this selectivity difference to the different binding modes of the GLOH intermediate on the two surfaces.

In order to understand whether this selectivity pattern can be extended to longer polyols, we study here the electrooxidation of the C₄ polyols. Polyols with four carbons (Figure 1) are the simplest polyols containing primary and secondary carbons as well as a pair of diastereomers, allowing to investigate the effect of the spatial orientation of the OH groups on the electrooxidation reaction.

The C₄ polyols may serve as model molecules to understand the electrochemical behavior of important biomass feedstocks with longer carbon chains such as sorbitol, ribitol, xylitol and the corresponding acids and aldehydes.⁷

Figure 1. Structural comparison of the C_4 polyols. The molecular structure of $GlOH$ does not permit the existence of isomers. Threitol has two enantiomers (which are diastereomers of erythritol). Erythritol and its mirror image are the same molecule.

In this paper, we study the electrochemical oxidation of the C_4 polyols on Pt(111), Pt(100) and Pt(110) electrodes and the stability of the double-dehydrogenated C_4 intermediates on Pt(111), Pt(100) and Pt(110) using voltammetry, *in situ* infrared spectroscopy, and first-principles density functional theory (DFT) calculations.

The experiments show that while Pt(110) selectively oxidizes the primary carbon, Pt(111) and Pt(100) produce both the acid (oxidation of the primary carbon) and the ketone (oxidation of the secondary carbon), with the ratio ketone/acid being higher for Pt(111).

The DFT calculations suggest that the production of the ketone is related to the ability of the surface to stabilize an enediol intermediate. Finally, erythritol and threitol show exactly the same oxidation characteristics, permitting us to conclude that the reaction is not sensitive to the OH group orientation.

EXPERIMENTAL SECTION

Electrochemical System and Surface Preparation. All electrochemical measurements were performed at room temperature (25 ± 1 °C) in a conventional three-electrode cell. A platinum foil and a reversible hydrogen electrode were used as counter and reference electrode, respectively. All potentials were measured versus a reversible hydrogen electrode (RHE) in contact with the blank electrolyte. The working electrodes were Pt(111), Pt(110), and Pt(100) acquired from Icryst. Before each experiment, the electrodes were flame annealed and cooled in an $H_2 + Ar$ atmosphere. Subsequently, the electrode was transferred to an electrochemical cell with the surface protected by a droplet of ultrapure water saturated with the Ar/H_2 mixture, thus avoiding contamination and reconstruction of the surface during its transfer to the electrochemical cell.^{20,21}

In order to verify the ordering of the electrode surface, cyclic voltammograms were acquired between 0.05 and 0.80 V in N_2 -saturated $0.1 \text{ mol L}^{-1} HClO_4$ solution at 50 mV s^{-1} . Next, the electrode was transferred to another cell containing 5 mmol L^{-1} polyol (erythritol or D-threitol) in $0.1 \text{ mol L}^{-1} HClO_4$ solution. The linear positive potential sweep were obtained from 0.05 to 0.9 V at 1 mV s^{-1} . The D-threitol was used because the racemic mixture, also commercially available, has lower purity.

In Situ FTIR. Spectra were acquired using a Shimadzu IR Prestige-21 equipped with a mercury–cadmium telluride (MCT) detector. A homemade spectroelectrochemical cell, with a CaF_2 window, was attached to a specular reflection accessory (Veemax II, Pike Technologies). Before each experiment, the electrodes were prepared as described in the

previous section. All spectra were recorded with an average of 256 interferograms and 4 cm^{-1} resolution during chronoamperometry experiments at potentials between 0.1 and 0.7 V. The electrolyte was a N_2 -saturated $0.1 \text{ mol L}^{-1} HClO_4$ solution containing 5 mmol L^{-1} polyol (erythritol or D-threitol). Finally, all absorbance spectra were plotted as the ratio R/R_0 , where R_0 is the reference spectrum collected at 0.1 V and R is the spectrum obtained as a function of the applied potential, including the spectrum recorded at 0.1 V.

For product detection, we also performed electrolysis and HPLC analysis. However, the low amount of products detected did not permit to extract reliable conclusions.

Chemicals. All solutions were made with ultrapure water ($18.2 \text{ M}\Omega \text{ cm}^{-1}$, 25 °C, Millipore), and chemicals were used without any prior purification. The chemicals used were perchloric acid (97%, 99.999% trace metals basis Sigma-Aldrich), D-threitol (99%, Sigma-Aldrich), meso-erythritol ($\geq 99\%$, Sigma-Aldrich), D-erythronic acid γ -lactone (95.0%, Sigma-Aldrich), L-(+)-erythulose ($\geq 85\%$, HPLC, Sigma-Aldrich), and deuterium oxide (99.9% atom% D, Sigma-Aldrich).

Computational Methods. Atomistic computer simulations were performed based on DFT using the VASP code (Vienna ab initio simulation package).^{22–24} The Kohn–Sham equations^{25,26} were solved using a periodic approach along the three directions with a plane-wave basis set. For the exchange–correlation functional we used the generalized gradient approximation (GGA) with the parametrization of Perdew–Burke–Ernzerhof (PBE).²⁷ The effects of van der Waals interactions were taken into account by using Grimme’s corrections to the PBE functional (PBE+D3).^{28,29} The PAW method^{30,31} was applied for the description of the core electrons.

The computational work focused on five double dehydrogenated adsorbed species derived from the erythritol which were bound to the three Pt single crystal basal planes (Figure 2). The intermediate doubly dehydrogenated at the C1 is

Figure 2. Overview of the five erythritol derived structures adsorbed on the Pt(100) surface and the numbering of the carbon atoms in the erythritol molecule.

named intermediate 1; the others were dehydrogenated in two different carbons, on C1 and C2, C1 and C3, C2 and C3, and, finally, C1 and C4, and named intermediates 2, 3, 4, and 5, respectively.

The calculations include the free platinum surfaces, the adsorption systems and the isolated molecules of erythritol and H_2 . The molecule was constructed in a nonsymmetric box of $20 \times 21 \times 19 \text{ \AA}$. From the equilibrium lattice constant of 3.967 \AA found for the Pt bulk (deviation of 1.2% from experimental

measure³²), we created slab models for the (100), (111), and (110) Pt surfaces, with 4×5 , 4×4 , and 3×5 cells and 6, 5, and 5 atomic layers, respectively. The bottom two layers were kept fixed during geometry optimizations and a vacuum distance of 20 Å was set to guarantee a negligible interaction between slab surfaces.

During the simulations, the orientation of the hydroxyl groups proved to be important. Therefore, we explored several different structures in order to obtain the most favorable ones. For the optimization we employed a plane-wave cutoff energy of 450 eV and a $3 \times 3 \times 1$ k-points sampling, generated with the Monkhorst–Pack method. The convergence criteria were 0.01 eV/Å for the forces and 10^{-6} eV for the electronic energy. The static calculations were performed with a $6 \times 6 \times 1$ k-points mesh also generated using the Monkhorst–Pack method.

The energy trends of the intermediates on the three platinum surfaces was studied from the adsorption energies (ΔE_{ads}), calculated as follows:

$$\Delta E_{\text{ads}} = E_{\text{Pt-surface+intermediate}} - (E_{\text{Pt-surface}} + E_{\text{Erythritol}} - E_{\text{H}_2}) \quad (1)$$

where $E_{\text{Pt-surface+intermediate}}$ presents the energy of the adsorbate–substrate system, $E_{\text{Pt-surface}}$ represents the total energy of the Pt surface, $E_{\text{Erythritol}}$ represents the total energy of the free erythritol molecule, and E_{H_2} represents the total energy of free H_2 .

The free energies of adsorption (ΔG_{ads}) were obtained by adding vibrational zero-point energy (ΔE_{ZPE}) and vibrational entropy corrections (ΔS) to the adsorption energies (eq 2). In order to calculate the free energies of adsorption, the most favorable structures were selected and the calculation of their vibrational frequencies were performed using density functional perturbation theory methodology (DFPT).^{33,34}

$$\Delta G_{\text{ads}} = \Delta E_{\text{ads}} + \Delta E_{\text{ZPE}} - T\Delta S \quad (2)$$

During the vibrational calculations, almost all surface atoms were kept frozen (the free energy variation of the platinum atoms was disregarded), except those involved in bonds, whereas the adsorbates were allowed to vibrate. The same was done for the free erythritol molecule and for H_2 . The zero-point energy term was obtained through half of the sum of the vibrational frequencies multiplied by the Planck constant while the entropy change was computed from statistical mechanics³⁵ considering the vibrational contribution but neglecting the translation contribution. This apparently strong approximation is acceptable when considering that all intermediates in gas phase should have similar translation entropy values, which must decrease to negligible values upon adsorption. Consequently, the translation entropy change has a similar contribution in all intermediates, and it is expected that it will not modify the trends reported here.

RESULTS

Electrochemical and Spectroscopic Results. Figure 3 shows the cyclic voltammetry of the electrooxidation of erythritol and threitol. Both molecules show similar voltammetric features which resemble the results obtained with glycerol,^{19,36} i.e., the onset potential is higher for Pt(100) than for Pt(111) and Pt(110). Pt(100) shows a sharper current peak and Pt(110) shows the lowest peak current.

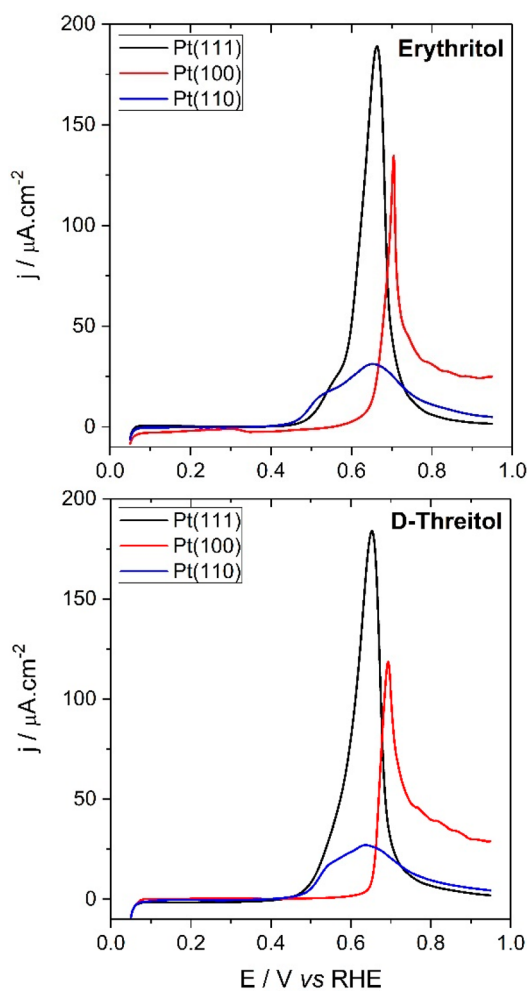

Figure 3. Positive-going sweep of the 1st cycle of the voltammetric response for the erythritol and D-threitol oxidation in 0.1 mol L⁻¹ HClO_4 + 5 mmol L⁻¹ polyol on Pt(111) and Pt(100). Sweep rate of 1 mV s⁻¹.

As in this work we are mainly interested in studying the selectivity of erythritol and threitol oxidation without C–C bond breaking, we performed FTIR experiments in D_2O , as this solvent (compared to water) does not present bands in the region 1400–2000 cm^{-1} , and therefore, the region of the stretching due to carbonyl containing compounds is easier analyzed than in water.

Figure 4 shows FTIR spectra obtained during the positive-going sweep for the oxidation of erythritol on the three-platinum single-crystal electrodes. The spectra show three main bands: at 1780 cm^{-1} (belonging to erythronic acid), at 1730 cm^{-1} (due to the formation of erythrulose), and a feature at 1100 cm^{-1} due to the entrance of ClO_4^- anions in the thin layer. Figure S1 in the Supporting Information shows the transmission spectra for the dissolved reactants and products.

Figure 4 shows the impact of the Pt surface on the selectivity of the oxidation of the primary and secondary carbon of the C_4 polyols. On Pt(111), we observe the bands corresponding to both erythrulose and to erythronic acid (see also Figure S2). On Pt(100) the bands corresponding to the oxidation products appear at higher potentials, in concordance with the electrochemical results. We observe again the production of erythrulose and erythronic acid, but in this case the relative intensity of the bands is inverted, with more primary oxidation

Figure 4. FTIR spectra taken at different electrode potentials (vs RHE) for the EOP in $0.1 \text{ mol}\cdot\text{L}^{-1} \text{ HClO}_4 + 5 \text{ mmol}\cdot\text{L}^{-1}$ erythritol on Pt(111), Pt(100) and Pt(110). The potential was scanned up to 0,6 V for Pt(111) and 0,7 V for Pt(100) and Pt(110) and was held at these values to obtain 10 consecutive spectra for Pt(111) and 20 consecutive spectra for Pt(100) and Pt(110), to maximize the signal of the products obtained at those potentials. Figure S4–S6 show similar experiments but holding the potentials at other values.

product (see also Figure S3). Finally, Pt(110) oxidizes selectively the primary carbon (see also Figure S4). Experiments in Figures S2–S4 in the Supporting Information are the same as in Figure 4, but also spectra at other potentials were taken. These results permit us to conclude that the relative quantities of acid and ketone produced do not depend on the electrode potential (at least in the potential domain where we performed this study).

Figures S6 and S7 in the Supporting Information show the spectra obtained during the electrooxidation of erythritol and threitol on the three surfaces in nondeuterated water. All the spectra show an intense band at 2343 cm^{-1} due to the complete oxidation of the polyol to CO_2 , bands related to the presence of on top and bridge-bonded CO, and a band at 1780 cm^{-1} due to the production of the carboxylic acid. More details can be found in the Supporting Information. These results show that there is a pathway that produces CO_2 , either through a previous formation of CO or through the oxidation of formic acid, as in the case of GIOH oxidation.¹¹ These results are similar to those found with many other small organic molecules. Another important result is that in concordance with the electrochemical results in Figure 3, the FTIR spectra were very similar for erythritol and threitol (Figures S5 and S6).

Computational Experiments (DFT). Figure 5 shows the most stable configurations for the adsorbates of erythritol on the three Pt basal planes and the corresponding adsorption energies (ΔE_{ads}) are plotted in Figure 6. Since the C_4 polyol has more degrees of freedom than GIOH (studied in ref 19), many more configurations were studied in this work (Figure S7). We have not calculated activation barriers for adsorption as this would require very severe approximations. Our aim is a qualitative comparison, for which knowing the stability of intermediates is typically sufficient.³⁷ Figure S8 shows ΔE_{ads} and ΔG_{ads} using the PBE functional. The results show that

both ΔE_{ZPE} and $T\Delta S$ do not change the relative energies of the intermediates.

There is a clear trend for all the intermediates. The more open the surface is (i.e., surface atoms with lower coordination number), the stronger the adsorption of the intermediates is. This trend is common³⁸ and has been observed by other researchers in similar systems.^{15,39,40} It is noteworthy in Figure 5 that most configurations tend to maximize the OH-surface interactions, allowing the carbon chain to adopt a configuration almost parallel to the platinum surface. As a result, Figure 6 shows that intermediate 3 is the most stable for all three surfaces. Besides, its energy difference with respect to the others intermediates show the trend Pt(110) > Pt(100) > Pt(111). Intermediate 5 is the least stable for all surfaces and intermediates 1 and 2 have rather similar energies. An important difference arises when analyzing intermediate 4. While it is relatively unstable in Pt(110) and Pt(100), it is the second most stable intermediate in Pt(111), due to a relatively higher stabilization by van der Waals interaction (compare Figure S8 and Figure 6).

DISCUSSION

The electrochemical and FTIR results show very similar responses for erythritol and threitol. Therefore, we conclude that the EOP is not sensitive to the spatial orientation of the $-\text{OH}$ in the secondary carbon. This insensitivity to the orientation of the OH groups is in contrast with previous work,⁷ which may be due to different sources of threitol, though this hypothesis would require further study.

FTIR shows that Pt(111) and Pt(100) produce the ketone and the acid, however the selectivity ratio ketone/acid is higher for Pt(111). These findings are in line with those published by Garcia et al.¹⁷ for GIOH. Besides, we extended the results to Pt(110) and found that this surface is completely selective to the oxidation of the primary carbon.

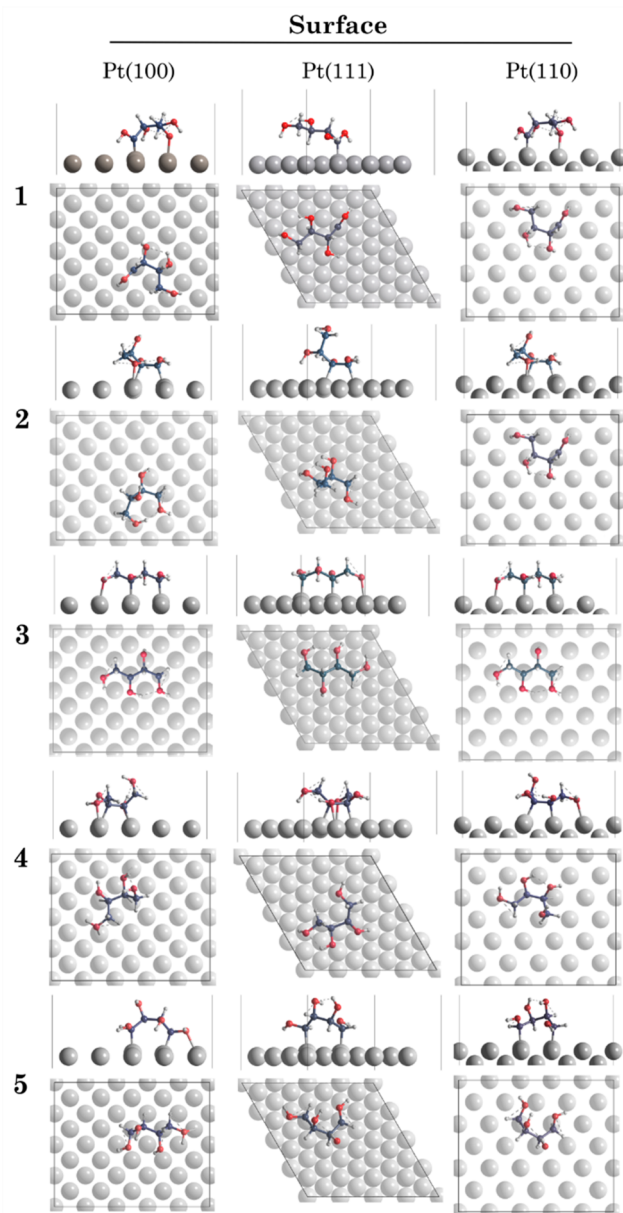

Figure 5. Top and side views of the most stable intermediates for Pt(100), Pt(111), and Pt(110) surfaces.

To compare the computational results obtained with GIOH and erythritol, Figure 7 shows the structures of the intermediates proposed in ref 19, the equivalent structures for the erythritol and the intermediate 4.

Garcia et al.¹⁹ explained the higher ability for the oxidation of the secondary carbon of GIOH on Pt(111) by the more favorable adsorption energy of intermediate 2 (which is essentially an enediol) compared to intermediate 1 (considered the precursor of the aldehyde, which is easily oxidized to form the acid). The formation of the (adsorbed) enediol intermediate was considered crucial for the formation of the ketone (dihydroxyacetone in the case of glycerol oxidation), as the enediol is the key intermediate in the isomerization between the aldehyde and the ketone, and the ketone is the thermodynamically most stable isomer.⁴¹ In addition, for erythritol, we consider that the intermediate 4 could be also a precursor of the ketone.

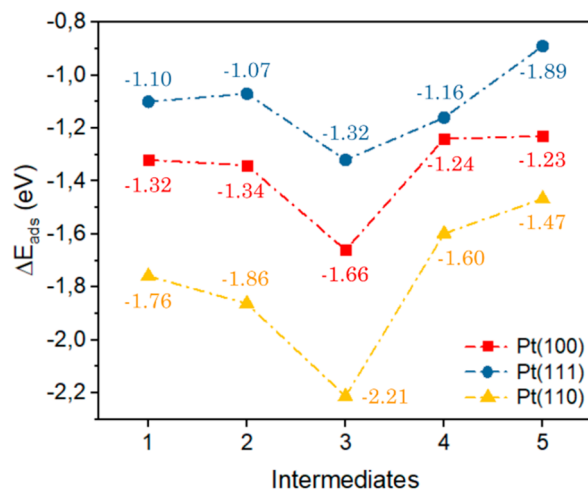

Figure 6. Adsorption energies for the five intermediates on Pt(100), Pt(111), and Pt(110).

Figure 7. Side views of the double dehydrogenated intermediates 1, 2, and 3 of GIOH and 1, 2, 3, and 4 of erythritol.

As stated in ref 19, intermediate 3 can be a precursor for a pathway toward the production of C1 and C2 molecules, but our results strongly suggest that it can be also oxidized to produce the acid. Its high stability explains the presence of this product on all surfaces, besides, the large difference in energy of intermediate 3 with the other intermediates explains the fact that Pt(110) selectively oxidizes the primary carbon.

Taking the stability of the (adsorbed) intermediates 2 and 4 compared to the stability of intermediate 3 as a measure for the relative selectivity to secondary alcohol oxidation, we see that the adsorption energies in Figure 6 can explain the experimental trend. Intermediates 2 and 4 are closer in energy to intermediate 3 on Pt(111) than on Pt(100), explaining the higher selectivity of Pt(111) toward the oxidation of the secondary carbon.

It is generally assumed that Pt(110) is the most representative surface for polycrystalline Pt (Pt_p ; among the Pt basal planes). Consequently, this surface has shown a rather similar behavior to Pt_p for the electrooxidation of GIOH.^{42,43} Besides, it has been observed that several polyols (including GIOH and erythritol) are preferentially oxidized at their primary carbon on Pt_p .^{7,44} Extending this to other polyols, we expect that Pt_p will oxidize them to their corresponding carboxylic acid. Secondary alcohol oxidation requires the presence of (111) terrace sites, or the addition of promoters, which favorably interact with enediol intermediate.^{7,9,41,45}

CONCLUSION

Through electrochemical, spectroelectrochemical, and computational experiments, we have studied the oxidation of C₄ polyols on the Pt three basal planes.

The (spectro)electrochemical results showed that erythritol and threitol behave similarly, permitting us to conclude that the relative orientation of the OH groups do not play a role in the oxidation of these molecules.

Regarding the selectivity of the oxidation to the formation of the products without C–C bond breaking, we found that the more open the surface is, the higher the relative oxidation of the primary carbon. By comparing our results with those previously published with other polyols, we suggest that these selectivity patterns are more general and can be extended to longer polyols.

The DFT calculations suggested that the trends in selectivity are governed by the relative stability of the doubly dehydrogenated intermediates. Only the adsorbed intermediate with enediol character, i.e., binding to the surface with neighboring carbons can give rise to the formation of the ketone. We showed that the intermediates bound through the two secondary carbons have the relatively highest stability on Pt(111), explaining the relatively high production of the ketone on this surface. The most stable intermediate on all the surfaces binds through the primary and tertiary carbon, and we expect this intermediate to be a precursor for the formation of the acid.
