ABSTRACT

Using *Chandra* observations, we derive the Y_X proxy and associated total mass measurement, $M_{500}^{Y_X}$, for 147 clusters with $z \leq 0.35$ from the *Planck* Early Sunyaev-Zel'dovich catalog, and for 80 clusters with $z \leq 0.30$ from an X-ray flux-limited sample. We re-extract the *Planck* Y_{SZ} measurements and obtain the corresponding mass proxy, M_{500}^{SZ} , from the full *Planck* mission maps, minimizing the Malmquist bias due to observational scatter. The masses re-extracted using the more precise X-ray position and characteristic size agree with the published PSZ2 values, but yield a significant reduction in the scatter (by a factor of two) in the $M_{500}^{SZ} - M_{500}^{Y_X}$ relation. The slope is 0.93 ± 0.03 , and the median ratio, $M_{500}^{SZ} / M_{500}^{Y_X} = 0.91 \pm 0.01$, is within the expectations from known X-ray calibration systematics. The Y_{SZ} / Y_X ratio is 0.88 ± 0.02 , in good agreement with predictions from cluster structure, and implying a low level of clumpiness. In agreement with the findings of the *Planck* Collaboration, the slope of the $Y_{SZ} - D_A^{-2} Y_X$ flux relation is significantly less than unity (0.89 ± 0.01). Using extensive simulations, we show that this result is not due to selection effects, intrinsic scatter, or covariance between quantities. We demonstrate analytically that changing the $Y_{SZ} - Y_X$ relation from apparent flux to intrinsic properties results in a best-fit slope that is closer to unity and increases the dispersion about the relation. The redistribution resulting from this transformation implies that the best fit parameters of the $M_{500}^{SZ} - M_{500}^{Y_X}$ relation will be sample-dependent.

Keywords: galaxy clusters: general — cosmology: large-structure of universe

1. INTRODUCTION

Galaxy clusters reside in the highest ranges of the halo mass function. In the standard Λ CDM cosmology, massive halos form by the accretion of smaller sub-clumps (e.g., Jones et al. 1979; Forman & Jones 1982; Allen et al. 2011; Kravtsov & Borgani 2012). Under the influence of gravity, uncollapsed and collapsed sub-clumps fall into larger halos and, occasionally, objects of comparable mass merge with one another.

X-ray observations of substructures in galaxy clusters (see, for instance, Jones & Forman 1984, 1999; Mohr et al. 1995; Buote & Tsai 1996; Jeltama et al. 2005; Böhringer et al. 2010; Laganá et al. 2010; Andrade-Santos et al. 2012, 2013) and measurements of the growth of structure (Vikhlinin et al. 2009b; Mantz et al. 2010; Allen et al. 2011; Benson et al. 2013; Planck Collaboration XX 2014; Planck Collaboration XXIV 2016) show that these objects are still in the process of formation.

A well established relation between the cluster mass and its observables (such as X-ray luminosity, gas temperature, etc) is crucial to any work that explores the theoretical relation between the number density of collapsed halos (the mass func-

* Steve Murray passed away on 2015 August 10. Completing the *Chandra* observations would not have been possible without his invaluable contributions.

tion) and the underlying cosmological parameters (Vikhlinin et al. 2009b; Planck Collaboration XX 2014; Planck Collaboration XXIV 2016; Pratt et al. 2019). The relations between a cluster’s observables and its mass are a direct consequence of gravity, which is the main force driving cluster evolution (Kaiser 1986). Departures from the purely gravitational self-similar expectation are usually attributed to non-gravitational processes, such as radiative cooling, AGN feedback, etc. (e.g. Voit et al. 2005; Pratt et al. 2010).

The *Planck* satellite surveyed the entire sky across nine microwave frequency bands. The resulting data set allowed the detection of galaxy clusters through the thermal Sunyaev-Zel’dovich (SZ) effect (Sunyaev & Zeldovich 1972). The thermal SZ effect is the shift of the CMB spectrum towards higher frequencies caused by the inverse Compton scattering of the CMB photons by the hot electrons in the ICM. Being proportional to the line-of-sight integral of the ICM pressure, the SZ signal is expected to be closely related to the cluster total mass (e.g. da Silva et al. 2004; Pike et al. 2014), and the amplitude of its signal is independent of the cluster redshift, since the CMB photons were all emitted at a constant redshift of $z \sim 1000$. As a consequence, SZ surveys can potentially build unbiased cluster samples, covering higher redshifts than X-ray samples, and are expected to be close to mass-limited.

The second *Planck* catalogue (PSZ2, Planck Collaboration XXVII 2016), derived from the full High Frequency Instrument (HFI) survey of 29 months, detected 1653 cluster candidates. The vast majority (> 1200) of these candidates have been confirmed, making the PSZ2 catalog a reference for cluster studies. Among the many quantities provided by the PSZ2 catalog for each cluster, the mass estimate is arguably the most important. Since the *Planck* masses were determined using *XMM-Newton* data to calibrate the $Y_{SZ}-Y_X$ relation, comparing *Chandra* X-ray derived masses to SZ derived masses provides an independent and invaluable test for the *Planck* mass estimates.

Here we use *Chandra* observations to compute the masses for 147 *Planck* ESZ clusters at $z < 0.35$. All of the clusters have *Planck* SZ masses, and we compare these to the X-ray derived masses from our *Chandra* analysis. We compare the results with those obtained from observations of an X-ray selected sample of the 80 of the 100 highest flux X-ray clusters at Galactic latitudes $|b| > 20^\circ$ and $0.025 < z < 0.30$. We also study the $Y_{SZ}-Y_X$ relation. Our aim is to examine the $Y_{SZ}-Y_X$ relation and to compare X-ray and SZ masses for these clusters. We use the SZ-selected clusters as our baseline sample, and the X-ray-selected objects only for comparison. Examination of the impact of our findings on the *Planck* SZ cosmological constraints is beyond the scope of the present work.

Throughout this paper, we assume a standard Λ CDM cosmology with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.3$, and

$\Omega_\Lambda = 0.7$. The variables M_{500} and R_{500} are the total mass within R_{500} and radius corresponding to a total density contrast $\Delta = 500 \rho_c(z)$, where $\rho_c(z)$ is the critical density of the universe at the cluster redshift. The SZ flux is characterised by Y_{500}^{SZ} (in arcmin^2), or simply Y_{SZ} . The quantity $D_A^2 Y_{SZ}$ is then the spherically integrated Compton parameter within R_{500} (in Mpc^2), where D_A is the angular-diameter distance of the cluster. All uncertainties are quoted at the 1σ (68% confidence) level. The natural logarithm is denoted \ln , while \log denotes the decimal logarithm.

2. SZ AND X-RAY SELECTED CLUSTERS

For our investigation, we make use of the following cluster samples:

- An SZ-selected sample of clusters derived from the first catalog of 189 objects detected in the first 10 months of the *Planck* survey, and released in early 2011 (Planck Collaboration VIII 2011). A *Chandra* XVP (X-ray Visionary Program – PI: Jones) and HRC Guaranteed Time Observations (PI: Murray) were combined to form the *Chandra-Planck* Legacy Program for Massive Clusters of Galaxies. For each of the 164 ESZ *Planck* clusters at $z \leq 0.35$, we obtained *Chandra* exposures sufficient to collect at least 10,000 source counts¹.

The second *Planck* catalogue (PSZ2, Planck Collaboration XXVII 2016), derived from the full mission maps, provided masses for 157 of the original set of 163 ESZ clusters at $z \leq 0.35$. The remaining six clusters are not in the PSZ2 catalog, simply because they fall outside the mask used to construct that catalog (i.e. they are close to point sources). We can thus discard those without changing the sample selection function. We use the PSZ2 mass estimates of the resulting systems as they are largely independent of the original detection (discussed in more detail below). Of the resulting 157 clusters, nine are classed as multiple, defined as having more than one object (visually identified in the X-ray images) at a distance less than $10'$ from the main system. These were removed from the following as the presence of more than one system may lead to a boosting of the SZ signal due to confusion in the *Planck* beam. We also discarded the very nearby cluster PLCK-ESZ G234.59+73.01 (A 1367 at $z = 0.02$) as it is too large to allow a reliable background estimate in the *Chandra* pointing. Figure 1 displays a mosaic of the 147 clusters from the ESZ sample that were used in this work.

¹ hea-www.cfa.harvard.edu/CHANDRA.PLANCK.CLUSTERS/

Figure 1. Mosaic of the 147 clusters from the ESZ sample that were used in this work. Each cluster image was filtered to 0.5-2.0 keV, background-subtracted, exposure map corrected, binned to 4×4 pixels, and smoothed to 3 pixels. Image sizes are $3 \times R_{500}$ on a side, where R_{500} is obtained from the M_{500}^{YX} . Images are corrected for surface brightness cosmological dimming with redshift, and are displayed in logarithmic scale. The colour table and scale range is the same for all clusters, so that the images would be identical if clusters obeyed strict self-similarity. Order of clusters follows that from the machine-readable table available online, here in row-major order. Using standard matrix notation, examples are: the Bullet cluster in position c_{96} , Abell 3411 in position c_{81} , and Coma in position c_{33} .

- An X-ray selected sample of high-flux clusters. [Voevodkin & Vikhlinin \(2004\)](#) compiled a sample of the 52 X-ray brightest clusters in the local universe by selecting the highest flux objects detected in the ROSAT All-Sky survey at $|b| > 20^\circ$ and $z > 0.025$ – using the

HIFLUGCS² catalog as reference. The sample used here is an extension of [Voevodkin & Vikhlinin \(2004\)](#)'s approach, where the flux limit in the 0.5 – 2.0 keV band was lowered to $f_X > 7.5 \times 10^{-12}$ erg s⁻¹ cm⁻². The

² HIFLUGCS – The Highest X-ray FLUX Galaxy Cluster Sample ([Reiprich & Böhringer 2002](#); [Schellenberger & Reiprich 2017](#))

Figure 2. Same as Figure 1, except for the 80 clusters from the X-ray sample that were used in this work. Clusters that are also part of the ESZ sample used in this work are presented from the beginning (top left) until (and including) Abell 3667, which is displayed in position c_{46} .

full sample contains 100 clusters; the highest-redshift object is at $z = 0.215$. All have *Chandra* observations.

Eighty-three of the clusters from this sample have *Planck* SZ masses. Three of these were classified as multiple, according to the definition applied to the ESZ sample, so after removing these clusters we obtained a sample of 80 clusters. Of these, 45 are also in the ESZ sample, and 42 are in the HIFLUGCS sample. Figure 2 displays a mosaic of the 80 clusters from the X-ray sample that were used in this work.

The left panel of Figure 3 presents the redshift distribution of both cluster samples. The *Planck* detected clusters are clearly more broadly distributed in redshift than the X-ray clusters. This is due to the nature of the selection: for resolved clusters the Sunyaev-Zel’dovich signal is independent of the redshift of the cluster because it is the CMB that is distorted (the CMB photons originate at the epoch of recombination – from a constant redshift of $z \sim 1000$), while the X-ray selected clusters constitute a flux-limited sample, which strongly favors the X-ray brighter, lower redshift clusters. The right panel of Figure 3 presents the mass (derived using the Y_X proxy) distribution of both samples, showing that the X-

ray sample has on average lower mass than the *Planck* ESZ sample.

3. DATA REDUCTION

3.1. Chandra data

3.1.1. Event file processing

Our *Chandra* data reduction followed the process described in Vikhlinin et al. (2005). We applied the calibration files CALDB 4.7.2. The data reduction included corrections for the time dependence of the charge transfer inefficiency and gain, and also a check for periods of high background, which were then omitted. Standard blank sky background files and readout artifacts were subtracted. We also detected compact X-ray sources in the 0.7–2.0 keV and 2.0–7.0 keV bands using CIAO’s wavdetect and then masked these sources, as well as extended substructures, before performing the spectral and spatial analyses of the cluster emission. For each cluster, we used all available *Chandra* ACIS (ACIS-I and ACIS-S) observations within 2 Mpc from the cluster center. The median maximum radius of the observations is $1.53 R_{500}$ (with a maximum radius greater than R_{500} for 95% of the sample) and the median azimuthal coverage is $0.92 \pi R_{500}^2$. We have checked

Figure 3. The orange histograms show the X-ray flux limited sample, while the blue ones correspond to the ESZ cluster sample. Left: Distribution of cluster redshifts in the ESZ and the X-ray selected samples. The ESZ sample extends to higher redshifts than the X-ray flux-limited sample. Right: Distribution of cluster masses in the ESZ and X-ray selected samples. The X-ray sample extends to lower masses than does the ESZ sample.

that our results do not depend either on the maximum radius or on the coverage.

3.1.2. Emission measure profiles

We refer to [Vikhlinin et al. \(2006\)](#) for a detailed description of the procedures we used to compute the emission measure profile for each cluster. We outline here only the main aspects of the method.

We measured the surface brightness profiles in the 0.7–2.0 keV energy band, which maximizes the signal to noise ratio in *Chandra* observations for typical cluster gas temperatures. We used the X-ray peak as the cluster center. The readout artifacts and blank-field background (see section 2.3.3 of [Vikhlinin et al. 2006](#)) were subtracted from the X-ray images, and the results were then exposure-corrected, using exposure maps computed assuming an absorbed optically-thin thermal plasma with $kT = 5.0$ keV, abundance = 0.3 solar, with the Galactic column density and including corrections for bad pixels and CCD gaps, which do not take into account spatial variations of the effective area. We subtracted a small uniform component, corresponding to soft X-ray foreground adjustments, if required (determined by fitting a thermal model in a region of the detector field most distant from the cluster center, properly taking into account the expected thermal contribution from the cluster).

Following these steps, we extracted the surface brightness in narrow concentric annuli ($r_{\text{out}}/r_{\text{in}} = 1.05$) centered on the X-ray peak and computed the *Chandra* area-averaged effective area for each annulus (see [Vikhlinin et al. 2005](#), for details on calculating the effective area). To compute the emission measure and temperature profiles, we assumed spherical symmetry. The spherical assumption is expected to intro-

duce only small deviations in the emission measure profile ([Piffaretti et al. 2003](#)). Using the modeled de-projected temperature (see [Andrade-Santos et al. 2017](#)), effective area, and metallicity as a function of radius, we converted the *Chandra* count rate in the 0.7–2.0 keV band into the emission integral, $EI = \int n_e n_p dV$, within each cylindrical shell. Online tables in machine-readable format list the maximum cluster radius where the emission integral is computed (r_{max}) for each cluster. 142 (97%) clusters in the ESZ sample have $r_{\text{max}} > R_{500}^3$, and in the X-ray sample, 72 (90%) clusters satisfy this condition (four of the eight clusters that do not satisfy this condition are also in the ESZ sample). We have an average azimuthal coverage within R_{500} of $(0.8 \pm 0.2) \times \pi R_{500}^2$ for the ESZ clusters and $(0.6 \pm 0.2) \times \pi R_{500}^2$ for the X-ray clusters.

We fit the emission measure profile assuming the gas density profile follows that given by [Vikhlinin et al. \(2006\)](#):

$$n_e n_p = n_0^2 \frac{(r/r_c)^{-\alpha}}{(1 + r^2/r_c^2)^{3\beta - \alpha/2}} \frac{1}{(1 + r^\gamma/r_s^\gamma)^{\epsilon/\gamma}} + \frac{n_{02}^2}{(1 + r^2/r_{c2}^2)^{3\beta_2}}, \quad (1)$$

where the parameters n_0 and n_{02} determine the normalizations of both additive components. α , β , β_2 , and ϵ are indices controlling the slope of the curve at characteristic radii given by the parameters r_c , r_{c2} , and r_s . γ controls the width of the transition region given by r_s . Although the relation given by Equation 1 is based on a classic β -model ([Cavaliere &](#)

³ R_{500} defines the radius at the over-density of 500 times the critical density of the Universe at the cluster redshift. This quantity was obtained from the X-ray derived masses.

Figure 4. Example of the X-ray image (top panel), projected emissivity (lower left), gas density (lower center), and gas mass (lower right) profiles for the cluster PLCKESZ G000.44-41.83. Top panel shows the 0.5-2.0 keV, background-subtracted, exposure map corrected ACIS-I image. Black ellipses correspond to the masked X-ray point sources and the cross corresponds to the cluster center. Lower left panel shows the projected emissivity profile. The solid line shows the emission measure integral of the best fit to the emissivity profile given by Equation (1). Lower center panel shows the gas density profile. The solid line shows the density profile obtained from the emissivity profile given by Equation (1). Lower right panel shows the integrated gas mass profile $M_{\text{gas}}(< R)$, with the dashed vertical line indicating R_{500} . The dashed lines in the gas density and mass profiles show the 68% confidence range. This is an example of a cluster with moderate data quality, which illustrates the average data quality for the clusters in our samples. The total filtered *Chandra* exposure is 14 ks.

Fusco-Femiano 1976), it is modified to account for a central power-law type cusp and a steeper emission measure slope at large radii. In addition, a second β -model is included, to better characterize the cluster core. For further details on this equation, we refer the reader to Vikhlinin et al. (2006). In the fit to the emissivity profile, all parameters are free to vary. For a typical metallicity of $0.3 Z_{\odot}$, the reference values from Anders & Grevesse (1989) yield $n_e/n_p = 1.1995$. Examples

of projected emissivity and gas density profiles are presented in Figure 4.

3.1.3. Cluster Mass Estimates

Using the gas mass and temperature, we estimated the total cluster mass from the $M_{500}-Y_{500}^X$ scaling relation of Vikhlinin

et al. (2009a),

$$M_{500}^{Y_X} = E^{-2/5}(z) A_{YM} \left(\frac{Y_X}{3 \times 10^{14} M_\odot \text{keV}} \right)^{B_{YM}}, \quad (2)$$

where $Y_X = M_{\text{gas},500} \times kT_X$, $M_{\text{gas},500}$ is computed using the best fit parameters of Equation (1), and T_X is the measured temperature in the $(0.15-1) \times R_{500}$ range. We fit the spectrum in the 0.7–7.0 keV energy range with an absorbed APEC model, fixing NH to the total Galactic value (molecular plus atomic hydrogen contributions – Willingale et al. 2013). The parameters $A_{YM} = (5.77 \pm 0.20) \times 10^{14} h^{1/2} M_\odot$, and $B_{YM} = 0.57 \pm 0.03$ (Vikhlinin et al. 2009a). Here, $M_{500}^{Y_X}$ is the total mass within R_{500} , and $E(z) = [\Omega_M(1+z)^3 + (1 - \Omega_M - \Omega_\Lambda)(1+z)^2 + \Omega_\Lambda]^{1/2}$ is the function describing the evolution of the Hubble parameter with redshift. Using Equation (2), R_{500} is computed by solving

$$M_{500} \equiv 500 \rho_c (4\pi/3) R_{500}^3, \quad (3)$$

where ρ_c is the critical density of the Universe at the cluster redshift. In practice, Equation (2) is evaluated at a given radius, whose result is compared to the evaluation of Equation (3) at the same radius. This process is repeated in an iterative procedure, until the fractional mass difference is less than 1%. We estimated 1σ statistic uncertainties in the Y_{500}^X derived masses using Monte Carlo simulations. We also added to the Monte Carlo procedure a 1σ systematic uncertainty of 9% in the mass determination, as discussed by Vikhlinin et al. (2009a).

3.2. Planck data

3.2.1. Published masses

Derivation of the published *Planck* masses is extensively described in *Planck Collaboration XXVII* (2016). The mass was estimated from the relation between Y_{500}^{SZ} and M_{500} (*Planck Collaboration XX* 2014):

$$E(z)^{-2/3} \left[\frac{D_A^2 Y_{500}^{\text{SZ}}}{10^{-4} \text{Mpc}^2} \right] = 10^{-0.186} \left[\frac{h}{0.7} \right]^{-0.211} \left[\frac{M_{500}^{\text{SZ}}}{6 \times 10^{14} M_\odot} \right]^{1.789} \quad (4)$$

The SZ size-flux degeneracy was broken through the use of the scaling relation linking the SZ flux Y_{500}^{SZ} to the angular size, θ_{500} , that is then intersected with the two-dimensional posterior probability contours in the $(Y_{500}^{\text{SZ}}, \theta_{500})$ plane. For the PSZ2 masses, $M_{500}^{\text{SZ,PSZ2}}$, the $Y_{500}^{\text{SZ}}-\theta_{500}$ prior was obtained from the intrinsic relation between M_{500} and θ_{500} for a given redshift z :

$$\theta_{500} = \theta_* \left[\frac{h}{0.7} \right]^{-2/3} \left[\frac{M_{500}^{\text{SZ}}}{3 \times 10^{14} M_\odot} \right]^{1/3} E^{-2/3}(z) \left[\frac{D_A(z)}{500 \text{Mpc}} \right]^{-1}, \quad (5)$$

where $\theta_* = 6.997$ arcmin.

We recall that Equation (4) was calibrated on a baseline mass proxy relation linking the hydrostatic mass and the X-ray analog of the SZ Compton parameter, Y_{500}^X . As described in *Planck Collaboration XXVII* (2016), the resulting SZ mass $M_{500}^{\text{SZ,PSZ2}}$ can be viewed as the hydrostatic mass expected for a cluster consistent with the assumed scaling relation, at a given redshift, and given the measured $(Y_{500}^{\text{SZ}}, \theta_{500})$ posterior information. Hereafter we will refer to Y_{500}^{SZ} and Y_{500}^X simply as Y_{SZ} and Y_X .

3.2.2. Re-extracted masses

As discussed in Appendix A of *Planck Collaboration XI* (2011), a refined measurement of the SZ flux can be obtained by using higher-quality prior information on the position and size of the cluster. Such information is readily provided by our *Chandra* observations. In the following, we refer to the re-extracted masses as $M_{500}^{\text{SZ,PSX}}$. The SZ signal was thus re-extracted from the six HFI temperature channel maps corresponding to the full *Planck* mission survey. We used full resolution maps of HEALPix (*Górski et al. 2005*)⁴ $N_{\text{side}} = 2048$ and assumed that the beams were described by circular Gaussians. We adopted beam FWHM values of 9.66, 7.22, 4.90, 4.92, 4.68, and 4.22 arcmin for channel frequencies 100, 143, 217, 353, 545, and 857 GHz, respectively. Bandpass uncertainties were taken into account in the flux measurement. Uncertainties due to beam corrections and map calibrations are expected to be small, as discussed extensively in *Planck Collaboration VIII* (2011), *Planck Collaboration IX* (2011), *Planck Collaboration X* (2011) and *Planck Collaboration XI* (2011).

We extracted the SZ signal using multi-frequency matched filters (MMF, *Herranz et al. 2002*; *Melin et al. 2006*). These require information on the instrumental beam, the SZ frequency spectrum, and a cluster profile; noise auto- and cross-spectra are estimated directly from the data. We used the MMF in a targeted mode, extracting the SZ flux from a position centered on the X-ray emission peak using the “universal” pressure profile of *Arnaud et al. (2010)* as a spatial template, in an aperture θ_{500} corresponding to the R_{500} determined in Sect. 3.1.3 above. The extraction was achieved by excising a $10^\circ \times 10^\circ$ patch with pixel size 1.72, centered on the X-ray position, from the six HFI maps, and estimating the SZ flux using the MMF. The profiles were truncated at $5 R_{500}$ to ensure integration of the total SZ signal. The flux and corresponding error were then scaled to R_{500} using the profile assumed for extraction, yielding the refined estimate of Y_{SZ} . The resulting refined mass estimate $M_{500}^{\text{SZ,PSX}}$ was calculated as described above, using the $M_{500}^{\text{SZ}}-Y_{\text{SZ}}$ relation and the measured $(Y_{\text{SZ}}, \theta_{500})$ posterior information.

3.3. Fitting Procedure

We fit each scaling relation between a pair of observables (X, Y) with a power law of the form

$$Y/Y_0 = A[(X/X_0)]^B \quad (6)$$

assuming no evolution, as expected in the self-similar model. The reason for the latter decision is that the redshift leverage is insufficient to put a strong constraint on the evolution because the maximum redshift of the sample is $z < 0.35$. Figure 5 shows that the data are consistent with no evolution in the

Figure 5. Ratio between Y_{SZ} and Y_X , plotted as a function of $E(z)$. The white dashed line and grey envelope show the error-weighted mean and associated 1σ uncertainty, $Y_{SZ}/Y_X = 0.88 \pm 0.02$.

current sample. The pivot points X_0, Y_0 were $7 \times 10^{14} M_\odot$, $6 \times 10^{-5} \text{ Mpc}^2$, and $3 \times 10^{-3} \text{ arcmin}^2$ for M , Y [Mpc^2], and Y [arcmin^2] respectively.

The fit was undertaken using linear regression in the log–log plane, taking the uncertainties in both variables into account and intrinsic scatter. The X-ray and SZ measurements are independent, so there is no covariance between statistical errors for the scaling laws studied here.

We used the orthogonal Bivariate Correlated Errors and intrinsic Scatter (Akritas & Bershadsky 1996, BCES) linear regression method to perform the baseline fits. BCES is widely used by the astronomical community, giving results that may easily be compared with other data sets fitted using the same method. The intrinsic vertical scatter was computed from the quadratic difference between the raw scatter and that expected from the statistical uncertainties, as described in Pratt et al. (2009) and Planck Collaboration XI (2011).

We also fit the data using a Bayesian maximum likelihood estimation approach, with Markov Chain Monte Carlo (MCMC) sampling. Using the emcee package developed by Foreman-Mackey et al. (2013), we write the likelihood as described by Robotham & Obreschkow (2015).

$$\ln L = \sum_{i=1}^N \left[\ln \frac{B^2 + 1}{\sigma_i^2} - \frac{(\ln(Y_i/Y_0) - \ln A - B \ln(X_i/X_0))^2}{\sigma_i^2} \right] \quad (7)$$

$$\sigma_i^2 = \sigma^2 + B^2 \sigma_{X,i}^2 + \sigma_{Y,i}^2 \quad (8)$$

with the intrinsic scatter, σ^2 , as a free parameter. For comparison, we also used the LINMIX (Kelly 2007) and LIRA (Sereno 2016) Bayesian regression packages. The latter allows to correct for the Eddington bias due to the non-uniform

distribution of the covariate in the presence of intrinsic scatter (Sereno & Ettori 2015; Sereno 2016). We used the option `sigma.XIZ.0='prec.dgamma'` and a single Gaussian component for the corresponding latent variable. (We checked that adding an additional component does not change the results).

The fit results are detailed in Table 3, where it can be seen that the differences in slope and normalization between methods are always less than the 1σ statistical error on the parameters. We also note the excellent agreement between LIRA and BCES, suggesting that the Eddington bias due to the non-uniform distribution in the X variable is not an issue.

Table 3 also gives the mean ratio between SZ and X-ray quantities. This was computed by maximizing the likelihood of the logarithm of the ratios in log-log space, taking into account the statistical errors and an intrinsic scatter. We also computed the ratio by weighting each value of the logarithm ratio by the quadratic sum of the statistical error and the intrinsic scatter. This scatter and the weighted mean were then estimated simultaneously by iteration. Both methods give consistent results.

In Planck Collaboration XXIX (2014), the $Y_{SZ}-Y_X$ relation for the PSZ1 catalog was corrected for the Malmquist bias affecting the Y_{SZ} determination (see their Figure 32). The correction was made on a cluster-by-cluster basis, following the approach proposed by Vikhlinin et al. (2009a). The clusters in our study are from the ESZ catalog, which were detected in the Planck maps corresponding to the first 10 months of the survey. However, here we use the SZ signal from the PSZ2 catalog, re-extracted from the full mission maps. Although the maps are not fully independent, they correspond to significantly different noise realizations and we thus expect the re-extracted SZ signal from the PSZ2 maps to be much less affected by Malmquist bias than the original ESZ detection signal. As a first approximation, in the following we assume that the SZ signal is independent of the detection and neglect residual selection effects from Malmquist bias. We discuss the impact of this assumption extensively in Sect. 5.1 and Appendix A.

4. RESULTS

4.1. The $Y_{SZ}-Y_X$ relation

The total cylindrical Sunyaev-Zel'dovich signal is given by the integral of the Compton parameter, $Y_{SZ} = \int y d\Omega$, where Ω is the solid angle, and the Compton parameter y is given by:

$$y = \frac{\sigma_T}{m_e c^2} \int_l n_e k T_e dl, \quad (9)$$

where σ_T is the Thomson cross section, $m_e c^2$ is the electron rest mass energy, l is the distance along the line of sight, and k is the Boltzmann constant. The total Sunyaev-Zel'dovich signal within R_{500} can also be expressed as (in its spherical

Figure 6. The Y_{SZ} - Y_X relation for the ESZ sample. Left: Correlation between $D_A^2 Y_{SZ}$ and Y_X in units of Mpc², and comparison with previous works. Right: Correlation between Y_{SZ} and $D_A^{-2} Y_X$ in units of arcmin². The SZ signal is re-extracted in the full-mission maps at the X-ray position and size.

Figure 7. Comparison between X-ray and SZ derived masses for clusters in the PSZ2 sample. Left: *Planck* mass published in the PSZ2 catalog, $M_{500}^{\text{SZ,PSZ2}}$, iteratively estimated from the $M_{500}^{\text{SZ}}-Y_{SZ}$ relation and the Y_{SZ} - size degeneracy curve. The X-ray mass is derived from *Chandra* data using the Y_X mass proxy. Right: Same with SZ signal and masses re-extracted at the X-ray position and size, $M_{500}^{\text{SZ,PSX}}$. The blue and red lines correspond to the identity and the best fit power law, respectively. The red regions correspond to the $\pm 1\sigma$ uncertainty and scatter around the best fit. The gray regions correspond to the $\pm 2\sigma$ intrinsic scatter.

NOTE— $c^* = (\sigma_T/m_e c^2)/(\mu_e m_p)$. Relations are expressed as $Y/Y_0 = A[(X/X_0)]^B$ (Eq. 6). The pivot points X_0, Y_0 were $7 \times 10^{14} M_\odot$, $6 \times 10^{-5} \text{ Mpc}^2$ and $3 \times 10^{-3} \text{ arcmin}^2$ for M , $(D_A^2 Y_{SZ}, Y_X)[\text{Mpc}^2]$, and $(Y_{SZ}, D_A^{-2} Y_X)[\text{arcmin}^2]$, respectively. For all the relations $\sigma_{\ln,i}$ is the intrinsic scatter in log-log space (not given for LIRA, which constrains the intrinsic scatters of each variable with respect to the latent variable).

form)⁵ :

$$Y_{SZ} = \frac{\sigma_T}{D_A^2 m_e c^2} \int_V n_e k T_e dV, \quad (10)$$

⁵ The Planck Collaboration performed the Compton integral within a sphere, instead of performing it along the line of sight to infinity (cylindrical integral).

where D_A is the angular size distance of the cluster and V is the sphere of radius R_{500} .

The X-ray analog of the Sunyaev-Zel'dovich Compton parameter is defined as $Y_X = M_{\text{gas}} \times k T_X$, where M_{gas} is the gas mass given by:

$$M_{\text{gas}} = \int_V \rho_{\text{gas}} dV = \mu_e m_p \int_V n_e dV, \quad (11)$$

where μ_e is the mean molecular weight per electron, m_p is the proton mass, and T_X is the X-ray measured temperature in the $(0.15-1.0) \times R_{500}$ radial range.

On the other hand, the mass-weighted temperature is given by:

$$T_{\text{mw}} \equiv \frac{\int_V n_e T_e dV}{\int_V n_e dV}, \quad (12)$$

which, when combined with Equations 9 and 11, results in:

$$D_A^2 Y_{SZ} = c^* M_{\text{gas}} T_{\text{mw}}, \quad (13)$$

where c^* is given by:

$$c^* = \frac{\sigma_T}{m_e c^2} \frac{1}{\mu_e m_p} = 1.38 \times \frac{10^{-5} \text{ Mpc}^2}{10^{14} \text{ keV } M_\odot}, \quad (14)$$

where we used $\mu_e = 1.1706$, which was calculated assuming a fully ionized plasma with metallicity of $0.3 Z_\odot$, and reference values from Anders & Grevesse (1989).

In practice, when computing M_{gas} , we used the fact that the emission measure is proportional to $\langle n_e^2 \rangle$, averaged in radial annuli, to estimate $\langle n_e \rangle^2$. For a uniform spherical gas distribution, $\langle n_e^2 \rangle = \langle n_e \rangle^2$, so one can recover the gas density. However, the reality is different, with typically $\langle n_e^2 \rangle > \langle n_e \rangle^2$. Defining the clumping factor as $Q = \langle n_e^2 \rangle / \langle n_e \rangle^2$, we have $M_{\text{gas}}^{\text{obs}} = Q M_{\text{gas}}^{\text{true}}$. By definition $Y_X = M_{\text{gas}}^{\text{obs}} T_X$, so we can write:

$$\frac{D_A^2 Y_{SZ}}{c^* Y_X} = \frac{1}{Q} \frac{T_{\text{mw}}}{T_X}. \quad (15)$$

The $Y_{SZ}-Y_X$ relation is thus a fundamental probe of the consistency of the SZ and X-ray signal. When extracted within the same aperture (here *Chandra* R_{500}), the ratio does not depend on any mass calibration. It depends on clumpiness, internal structure (mass weighted temperature versus spectroscopic temperature), and absolute calibration of X-ray measured temperature (see e.g. the discussion in Adam et al. 2017). The $Y_{SZ}-Y_X$ relation is expected to have a slope of one (if clusters are self-similar in shape), and a normalization less than one due to the radial dependence of the temperature. In the following, Y_X will refer to the quantity renormalised by the c^* factor (Eq. 14), ie. expressed in units of Mpc^2 .

The left-hand panel of Figure 6 shows the the $D_A^2 Y_{SZ}-Y_X$ relation, i.e. the correlation between the cluster physical

Figure 8. Top left: the $M_{500}^{SZ}-M_{500}^{Y_X}$ relation for X-ray selected clusters only. Top right: the $M_{500}^{SZ}-M_{500}^{Y_X}$ relation with SZ and X-ray selected clusters indicated. Bottom left: the $D_A^2 Y_{SZ}-Y_X$ relation, with SZ and X-ray selected clusters indicated. Bottom right: same as bottom left panel, except for the flux $Y_{SZ}-D_A^{-2} Y_X$ relation. The SZ signal is extracted at the X-ray position and size.

properties – the intrinsic Compton parameter and Y_X . The slope, $B = 0.96 \pm 0.03$, is consistent with unity at slightly more than one sigma, while the normalization is $A = 0.89 \pm 0.09$. The slope of the relation is consistent with that found by [Planck Collaboration XXIX \(2014\)](#), displayed in Figure 6 by the orange line, within the statistical errors. The relation found by [Rozo et al. \(2012\)](#) using *Chandra* data, shown in green in Figure 6, has a somewhat shallower slope.

However, the picture changes when the $Y_{SZ}-D_A^{-2} Y_X$ relation is plotted, i.e. when considering the observed SZ flux

(arcmin^2). When plotted this way, the slope is clearly not consistent with unity, $B = 0.89 \pm 0.01$. The effect is similar to, and in agreement with, that observed in [Planck Collaboration XXIX \(2014\)](#), $B = 0.91 \pm 0.02$, although at higher statistical precision (see their Section 7 and Appendix D).

4.2. Comparison between SZ and X-ray derived masses

We next investigated the relation between the published *Planck* masses, $M_{500}^{SZ,PSZ2}$, and those obtained from the *Chandra* data via the $M_{500}-Y_X$ relation, $M_{500}^{Y_X}$, as described above

in Section 3.1.3. The left-hand panel of Figure 7 compares the published *Planck* PSZ2 masses to those from *Chandra* for the 147 ESZ objects. The slope of the relation, $B = 0.93 \pm 0.03$, is less than unity at slightly more than the 2σ level. This translates into an $M_{500}^{\text{SZ}}/M_{500}^{\text{X}}$ ratio that decreases from ~ 0.99 to ~ 0.88 between $M_{500} = 2 \times 10^{14} M_{\odot}$ and $M_{500} = 10^{15} M_{\odot}$.

The right-hand panel of Figure 7 shows the SZ mass re-extracted at the X-ray position and size, $M_{500}^{\text{SZ,PSX}}$, compared to the *Chandra* values. The main effect is a decrease of the intrinsic scatter by about a factor of two (from 11% to 6%). The slope, $B = 0.93 \pm 0.02$ is unchanged, although the uncertainty is smaller as a result of the decreased scatter. As the X-ray mass is slightly higher than the PSZ2 mass, fixing the size to the X-ray value tends to increase the SZ mass on average, while extracting the SZ signal at the X-ray position has the opposite effect (the blind SZ signal is extracted at the position maximising the signal-to-noise). As a result the median SZ to X-ray mass ratio, $M_{500}^{\text{SZ}}/M_{500}^{\text{YX}} = 0.91 \pm 0.09$, is unchanged, within the statistical errors.

In the following, we use the $M_{500}^{\text{SZ,PSX}}$ value as reference, as it is directly physically related to the M_{500}^{YX} quantity, and we will refer to it as M_{500}^{SZ} .

4.3. X-ray selected clusters

Here we consider the effect of adding the X-ray selected clusters to the relations discussed above. These clusters are discussed only for comparison to the SZ-selected objects.

The top-left panel of Figure 8 shows the $M_{500}^{\text{SZ}}-M_{500}^{\text{YX}}$ relation for the X-ray selected clusters only. It can be seen that these objects clearly populate the low mass part of the plot, with the majority of the systems having $M_{500} < 5 \times 10^{14} M_{\odot}$. The effect of adding the SZ selected clusters, as shown in the right-hand panel of Figure 8, is to transform what was a relation with a slope slightly less than unity (i.e. the SZ selected clusters only) into one with a clear offset in normalization. For the full sample of SZ + X-ray selected clusters, the slope $B = 0.97 \pm 0.02$, and the median ratio $M_{500}^{\text{SZ}}/M_{500}^{\text{YX}} = 0.90 \pm 0.14$.

To shed light on the above, we can use the corresponding intrinsic $D_{\text{A}}^2 Y_{\text{SZ}}-Y_{\text{X}}$ relation, which is shown in the bottom-left hand panel of Figure 8. We observe that as expected, the SZ and X-ray selected objects are distributed in the $Y_{\text{SZ}}-Y_{\text{X}}$ plane in a similar fashion to their distribution in the $M_{500}^{\text{SZ}}-M_{500}^{\text{YX}}$ plane: the X-ray selected clusters tend to have higher Y_{X} values for a given $D_{\text{A}}^2 Y_{\text{SZ}}$.

The bottom-right hand panel of Figure 8 shows the $Y_{\text{SZ}}-Y_{\text{X}}$ relation expressed in apparent flux ($Y_{\text{SZ}}-D_{\text{A}}^{-2} Y_{\text{X}}$). Here we notice that the X-ray selected clusters follow the distribution of SZ selected systems, but are typically distributed towards higher values. This is a consequence of the X-ray selected systems being on average at lower redshift. As a result, when the relation is plotted in intrinsic quantities these systems are redistributed in the $Y_{\text{SZ}}-Y_{\text{X}}$ plane via the D_{A}^2 factor. As noted

in [Planck Collaboration XXIX \(2014\)](#), the shallower slope in arcmin² results in an overestimate of the dispersion about the relation in Mpc² as a result of this redistribution. This is discussed in more detail below.

5. DISCUSSION

The slope of the $Y_{\text{SZ}}-D_{\text{A}}^{-2} Y_{\text{X}}$ relation, $B = 0.89 \pm 0.01$, is in good agreement with that found by [Planck Collaboration XXIX \(2014\)](#), and points to a very significant departure from unity. This is not the case for the $D_{\text{A}}^2 Y_{\text{SZ}}-Y_{\text{X}}$ relation between intrinsic properties, indicating that the $Y_{\text{SZ}}/Y_{\text{X}}$ ratio variations are more related to the SZ flux than to the intrinsic Compton parameter. This suggests a measurement origin for deviation of the slope from unity, rather than a physical variation of the $Y_{\text{SZ}}/Y_{\text{X}}$ ratio (e.g. with mass). We first discuss possible measurement biases which may explain the slope, starting with a possible residual Malmquist bias.

5.1. Selection bias, scatter, and covariance

When studying scaling relations, the importance of taking into account measurement biases is well recognised (e.g. [Angulo et al. 2012](#)). Relations between observed quantities result from the power-law scaling of each observable with redshift and mass, the most fundamental cluster properties. The intrinsic scatter of each quantity around the mean relation may be correlated, through, for instance, a common physical origin. For a cluster sample constructed from a survey, an important measurement bias is the so-called Malmquist bias. It is most critical for the observable used for the detection, O_{det} , when it is measured from the survey data. At a given mass, clusters with values that are scattered to higher values of O_{det} , either by noise or by the intrinsic scatter between the observable and the mass, will be preferentially detected. The average value of O_{det} will be then biased high, particularly when close to detection threshold, affecting the apparent slope of any scaling relation with O_{det} . This effect is amplified by the nature of the mass function, the number of clusters increasing with decreasing mass ([Allen et al. 2011](#), see their Fig. 5).

One may wonder if the deviation from unity of the slope of the $Y_{\text{SZ}}-D_{\text{A}}^{-2} Y_{\text{X}}$ relation is not simply due to residual Malmquist bias. Such a residual bias may be due to correlation between the noise in the ESZ and PSZ2 maps, as well as the intrinsic scatter of the Compton parameter at given mass. The intrinsic scatter of the Y_{X} proxy with the underlying mass should also be considered, as should its probable correlation with the scatter in Y_{SZ} .

Appendix A describes extensive simulations that were designed to investigate these effects on the observed $Y_{\text{SZ}}-D_{\text{A}}^{-2} Y_{\text{X}}$ relation. These were based on the production of mock ESZ catalogs through the injection of simulated clusters, following the Tinker mass function, into the *Planck* 10-month maps. This was followed by the application of the MMF algorithm

to obtain the SZ detections above a $S/N = 6$, the threshold of the ESZ catalog. The detected clusters were then re-injected into the full mission maps and re-analysed by the MMF algorithm to extract their PSZ2 flux values. Ten mock catalogs were produced, with a total of 1657 detections. To investigate selection, scatter, and covariance effects, we assumed a Gaussian log-normal correlated distribution for $D_A^2 Y_{SZ}$ and Y_X at fixed mass M_{500} with a covariance matrix. The reference quantity at given mass, following exactly the scaling relation, was denoted Y_M . The $Y_{SZ}-D_A^{-2}Y_X$ relation of the mock data was then analysed exactly as for the real data. Introducing each effect successively (see Fig. 9), we found that:

- The residual Malmquist bias, due to the fact that the noise realisations of the ESZ and PSZ2 maps are not strictly fully independent, is negligible. The Y_{SZ} flux extracted from the PSZ2 map is unbiased as compared to the reference $D_A^{-2}Y_M$ value, in the absence of scatter. This is also confirmed by the absence of correlation, in the real data, between the Y_{SZ}/Y_X ratio and the S/N ratio of the ESZ detection at a given mass (Fig.10).
- There is a small residual Malmquist bias due to the scatter in the $D_A^2 Y_{SZ}-M_{500}$ relation. This is expected, as clusters detected above the ESZ survey threshold, because they are scattered up due to the intrinsic scatter, will still have a higher Y_{SZ} signal than the average in the PSZ2 maps. The importance of this effect on the $Y_{SZ}-D_A^{-2}Y_M$ relation depends on the relative magnitude of the ESZ noise and the intrinsic scatter, i.e. which effect drives the cluster detectability. For reasonable values of scatter derived from numerical simulations of cluster formation, the effect on the slope is modest, $\Delta B \sim -0.02$.
- Intrinsic scatter in the Y_X-M_{500} relation decreases the slope of the $Y_{SZ}-D_A^{-2}Y_X$ relation, as compared to the $Y_{SZ}-D_A^{-2}Y_M$ relation, by $\Delta B \sim -0.02$. We do not have a clear explanation of this effect, which cannot simply be due to a residual Eddington-like bias. However the likely correlation between the $D_A^2 Y_{SZ}$ and Y_X scatter *redresses* the slope back towards unity ($B = 0.973 \pm 0.005$). This is a well-known effect: selection bias due to intrinsic scatter has little impact on the relation between observables when clusters scatter almost along the relation (Angulo et al. 2012).

In summary, residual Malmquist bias due to *Planck* noise (statistical scatter) is negligible, and selection effects due to typical values of intrinsic scatter as predicted by numerical simulations cannot explain the observed behaviour of the $Y_{SZ}-D_A^{-2}Y_X$ relation.

An independent mass estimate (such as a lensing mass) is required to make further progress on this issue. This would enable one to constrain simultaneously the Y_X-M_{500} and $D_A^2 Y_{SZ}-M_{500}$ scaling relations and their intrinsic scatter, taking into account the *Planck* selection function. Such an approach, based on a full modelling of the maximum likelihood of the observed data (Y_{SZ} , Y_X and mass for each cluster) is now frequently applied to survey data (e.g. Stanek et al. 2006; Vikhlinin et al. 2009a; Mantz et al. 2010; Giles et al. 2016; Dietrich et al. 2019). Application of such a method to the current data set would be more complicated, however, as we would need to combine the detection in the ESZ maps with the measurement of the Y_{SZ} flux in the PSZ2 maps. Such a study is outside the scope of the paper.

5.2. Other measurement systematic effects

Following the tests performed in Section 5.1 and in Appendix A, indicating that selection effects cannot explain the slope of the $Y_{SZ}-D_A^{-2}Y_X$ relation, we next considered the possibility that its departure from unity is due to systematic issues with the Y_{SZ} or Y_X estimates. We therefore considered a range of possible explanations, including:

- Neglect of relativistic effects: in principle this effect is stronger in hotter, more massive clusters. It should thus be more apparent in the correlation between intrinsic properties, which is clearly not the case.
- Non Gaussian beams: the approximation of the *Planck* beam with a Gaussian may cause a loss of flux due to neglect of the side-lobes. This effect would be more important for the most extended objects (i.e. nearby or hot clusters). To test the magnitude of this effect, we re-extracted the Y_{SZ} values using the *Planck* effective beams available through the *Planck* Legacy Archive⁶. We found a median ratio of $Y_{SZ}^{\text{Gauss}}/Y_{SZ}^{\text{eff.}} = 1.00 \pm 0.02$, with essentially zero dependence on angular extent.
- Variation in profiles: as detailed in Section 3.2, re-extraction of the *Planck* flux is undertaken assuming the ‘universal’ pressure profile of Arnaud et al. (2010) as a fixed spatial template. It is well known that individual profiles may deviate significantly from this. Furthermore, nearer clusters are better resolved in the *Planck* maps than more distant objects, and so there may be a distance dependence in this variation. However, comparison of Y_{SZ} fluxes measured using a fixed ‘universal’ template and one based on the individual pressure profile yielded a best-fit slope and normalisation entirely consistent with unity (see Figure B.1 of Planck Collaboration Int. V 2013).

⁶ <https://pla.esac.esa.int/>

- X-ray temperature calibration issues: the observed good agreement in slope seen in Figure 6 between the present study and the previous work by [Planck Collaboration XXIX \(2014\)](#), which used *XMM-Newton* data, suggest, empirically, that this cannot explain the observed slope. Furthermore, as for the relativistic effect, any temperature-dependent systematics should be more visible in the correlation in Mpc^2 than in arcmin^2 , which is clearly not the case. The effect of *XMM-Newton* versus *Chandra* calibration on the scaling relations is further discussed Sec. 5.4.

In summary, none of the above possibilities explains why the slope of the $Y_{\text{SZ}}-Y_{\text{X}}$ relation is significantly less than unity when expressed in units of apparent flux (arcmin^2).

5.3. Link between the $M_{500}^{\text{SZ}}-M_{500}^{\text{Yx}}$ and the $Y_{\text{SZ}}-Y_{\text{X}}$ relations.

The slope of the intrinsic $D_{\text{A}}^2 Y_{\text{SZ}}-Y_{\text{X}}$ relation is significantly different from that of the $Y_{\text{SZ}}-D_{\text{A}}^{-2} Y_{\text{X}}$ relation, and is consistent with unity. The difference between the two relations is a conversion from flux to intrinsic properties, i.e. a linear rescaling of each quantity by the angular distance D_{A}^2 of each cluster. In Appendix C, we demonstrate analytically that this transformation results in a $D_{\text{A}}^2 Y_{\text{SZ}}-Y_{\text{X}}$ relation slope that is closer to unity, as observed ($B = 0.96 \pm 0.03$), and increases the dispersion about the relation. This effect is actually caused by re-ordering of the data from the $Y_{\text{SZ}}-D_{\text{A}}^{-2} Y_{\text{X}}$ plane to the $D_{\text{A}}^2 Y_{\text{SZ}}-Y_{\text{X}}$ plane, as already noted in Sec. 4.3 for X-ray clusters.

The properties of the $M_{500}^{\text{SZ}}-M_{500}^{\text{Yx}}$ relation, derived from the mass proxies M_{500}^{SZ} and M_{500}^{Yx} , originate in the properties of the intrinsic $D_{\text{A}}^2 Y_{\text{SZ}}-Y_{\text{X}}$ relation. One can translate between the two by making use of the $M_{500}-Y_{\text{X}}$ and the $M_{500}-D_{\text{A}}^2 Y_{\text{SZ}}$ relations. We can express the relations as follows:

$$\begin{aligned} D_{\text{A}}^2 Y_{\text{SZ}} &\propto (Y_{\text{X}})^{\alpha} \\ M_{500}^{\text{SZ}} &\propto (M_{500}^{\text{Yx}})^{\beta} \\ M_{500}^{\text{Yx}} &\propto (Y_{\text{X}})^{\gamma} \\ M_{500}^{\text{SZ}} &\propto (D_{\text{A}}^2 Y_{\text{SZ}})^{\delta}, \end{aligned} \quad (16)$$

where α , β , γ , and δ noting the slope of the relations above (only here). The above leads to $\beta = \alpha \times \delta / \gamma$. In this work we obtained $\alpha = 0.96 \pm 0.03$. From Equation 4 we have $\delta = 1/1.789 = 0.56$, and from [Vikhlinin et al. \(2009a\)](#) we have $\gamma = 0.57$, which leads to $\beta = (0.96 \pm 0.03) \times (0.56) / 0.57 = 0.94 \pm 0.03$, which is basically what one gets in Figure 7 from the direct fit. In other words, the deviation of the slope from unity is simply slightly amplified when considering the mass proxies, rather than the measured Y parameters, because the $M_{500}-D_{\text{A}}^2 Y_{\text{SZ}}$ and $M_{500}-Y_{\text{X}}$ relations do not have exactly the same slopes (although they are consistent). Furthermore, the logarithmic intrinsic scatter of the $M_{500}^{\text{SZ}}-M_{500}^{\text{Yx}}$ is $\sigma_{\text{ln},i} = 0.051$,

about γ times the intrinsic scatter of the $D_{\text{A}}^2 Y_{\text{SZ}}-Y_{\text{X}}$ relation, $\sigma_{\text{ln},i} = 0.092$, as expected.

5.4. Effect of X-ray temperature calibration and of a different $M_{500}-Y_{\text{X}}$ calibration

It is well-known that there is a systematic difference between the X-ray temperature derived from *Chandra* and *XMM-Newton* the former yielding temperatures $\sim 7\%$ larger than *XMM-Newton* in the mass range considered here ([Schellenberger et al. 2015](#)). Consistently, there is also a slight difference of $\sim 4\%$ in the normalisation of the $M_{500}-Y_{\text{X}}$ relations obtained by [Vikhlinin et al. \(2009a\)](#), which is used here, and that obtained by [Arnaud et al. \(2010\)](#). (The slope difference between the two relations of 0.01 ± 0.02 is completely negligible.) Here we estimate analytically the effect of using *XMM-Newton* data and the [Arnaud et al. \(2010\)](#) relation on the $Y_{\text{SZ}}-Y_{\text{X}}$ and $M_{500}^{\text{SZ}}-M_{500}^{\text{Yx}}$ relations.

5.4.1. Effect on measured quantities

We consider first the effect on Y_{X} and the corresponding mass M_{500}^{Yx} . We write the relation as $M_{500}^{\text{Yx}} = A Y_{\text{X}}^B$, with $Y_{\text{X}} = M_{\text{g}}(r < R_{500}) T_{\text{X}}$. The quantities M_{500}^{Yx} and Y_{X} are estimated iteratively, and Y_{X} does not simply scale linearly with T_{X} as M_{g} depends sensitively on the aperture. For simplicity, we assume that the gas density is given by a β -model with $\beta = 2/3$, which leads to a gas mass $M_{\text{g}}(r < R_{500}) \propto R_{500}$. On the other hand, we can consider that the gas mass derived from *XMM-Newton* and *Chandra* data are the same ([Bartalucci et al. 2017](#)) and the core excised gas temperature T_{X} is not changed by a (small) change in aperture. Noting that $M_{500}^{\text{Yx}} \propto R_{500}^3$ by definition, we then obtain:

$$\begin{aligned} Y_{\text{X}} &\cong A^{1/(3-B)} T_{\text{X}}^{3/(3-B)} = A^{0.41} T_{\text{X}}^{1.23} \\ M_{500}^{\text{Yx}} &\cong A^{3/(3-B)} T_{\text{X}}^{3B/(3-B)} = A^{1.23} T_{\text{X}}^{0.70} \\ R_{500} &\cong A^{1/(3-B)} T_{\text{X}}^{B/(3-B)} = A^{0.41} T_{\text{X}}^{0.23} \end{aligned} \quad (17)$$

for $B = 0.57$ (Eq. 2).

The SZ quantities, Y_{SZ} and the corresponding M_{500}^{SZ} re-extracted within the X-ray aperture, will also be affected by the R_{500} aperture change. From our analysis of *Planck* data for the present sample, the variation of Y_{SZ} with aperture θ_{500} around the nominal θ_{500} value has a logarithmic slope of 0.8, so that:

$$Y_{\text{SZ}} \propto A^{0.8/(3-B)} T_{\text{X}}^{0.8*B/(3-B)} \quad (18)$$

The corresponding change in SZ mass, M_{500}^{SZ} , can be obtained from the $M_{500}-D_{\text{A}}^2 Y_{\text{SZ}}$ relation (Eq. 5). We can then insert the numerical values for the *Chandra* and *XMM-Newton* temperature difference and for the normalisation of the $M_{500}-Y_{\text{X}}$ relation: $T_{\text{X,CXO}} = 1.07 T_{\text{X,XMM}}$; $A_{\text{XMM}} = 0.96 A_{\text{CXO}}$ with $B = 0.57$. We then obtain $Y_{\text{X,XMM}} \sim 0.90 Y_{\text{X,CXO}}$, $M_{500,\text{XMM}}^{\text{Yx}} \sim 0.88 M_{500,\text{CXO}}^{\text{Yx}}$, $Y_{\text{SZ,XMM}} \sim 0.97 Y_{\text{SZ,CXO}}$ and $M_{500,\text{XMM}}^{\text{SZ}} \sim 0.99 M_{500,\text{CXO}}^{\text{SZ}}$.

5.4.2. Effect on the scaling relations

We can now estimate how these changes in cluster parameters would affect the $D_A^2 Y_{SZ}-Y_X$ and $M_{500}^{SZ}-M_{500}^{Y_X}$ relations. For constant multiplying factors that change Y_X , Y_{SZ} and corresponding masses, the slopes would not change, however, the normalizations would. We consider the following power-laws: $D_A^2 Y_{SZ} = A(Y_X)^\alpha$ and $M_{500}^{SZ} = B(M_{500}^{Y_X})^\beta$, with $\alpha = 0.96$ and $\beta = 0.93$ corresponding to the best fitting values (Table 3). The normalisation will change following the ratio of *XMM-Newton* and *Chandra* quantities, given above, as $A_{XMM} = A_{CXO} \times [0.97/0.90]^\alpha$, and $B_{XMM} = B_{CXO} [0.99/0.88]^\beta$. Had we used *XMM-Newton* data and [Arnaud et al. \(2010\)](#) $M_{500}-Y_X$ relation, we estimate that the slopes for the $Y_{SZ}-Y_X$ and the $M_{500}^{SZ}-M_{500}^{Y_X}$ relations would be the same, and the normalizations would be higher, by $\sim 7\%$ and 12% , respectively.

Finally, we compare our results with those from [Planck Collaboration XXIX \(2014\)](#). For comparison purposes, we express the $D_A^2 Y_{SZ}-Y_X$ relation using the pivot point of [Planck Collaboration XXIX \(2014\)](#), $Y_p = 10^{-4} \text{Mpc}^2$. In this work, we obtain $Y_{SZ}/Y_p = 0.87 \times (Y_X^{CXO}/Y_p)^{0.96}$. Using the estimated changes in slope and normalization for *XMM-Newton* data derived above, $\alpha_{XMM} = \alpha_{CXO}$ and $A_{XMM} = 1.07 A_{CXO}$, we obtain: $Y_{SZ}/Y_p = 0.93 \times (Y_X^{XMM}/Y_p)^{0.96}$, which is in perfect agreement with the result from [Planck Collaboration XXIX \(2014\)](#), $Y_{SZ}/Y_p = (0.94 \pm 0.02) \times (Y_X/Y_p)^{0.98 \pm 0.03}$. The *Planck* SZ masses were calibrated from the $Y_{SZ}-Y_X$ and $M_{500}-Y_X$ relations derived from *XMM-Newton* and the corresponding normalisation of the $M_{500}^{SZ}-M_{500}^{Y_X}$ relation is one by construction. The fact that we find a mean mass ratio (0.91 ± 0.09) 10% smaller than unity, is also consistent with the calibration differences.

In conclusion the impact of *XMM-Newton* versus *Chandra* calibration is small, but larger than the statistical errors on mean quantities. There is a good agreement in slope between the present study and previous study by [Planck Collaboration XXIX \(2014\)](#) based on *XMM-Newton* data. Differences in mean Y and mass ratio are consistent with *XMM-Newton* versus *Chandra* calibration.

5.5. Comparison to previous results

[Schellenberger & Reiprich \(2017\)](#) compared the *Planck* masses with masses derived assuming hydrostatic equilibrium (HE), for 50 clusters in common in the HIFLUCGS and PSZ2 catalogs. They derive a larger discrepancy between X-ray and SZ masses, with a very significant mass dependence (slope of $\alpha = 0.76 \pm 0.08$). They suggest that the differences at low masses can be due to Malmquist bias effect, in conjunction with and underestimate of the *Planck* masses at the high mass end. Our study does not confirm this trend. We emphasize that we showed that our study is free from Malmquist bias. On the other hand, the selection function of the sub-sample of

HIFLUCGS clusters discussed in [Schellenberger & Reiprich \(2017\)](#) is a complex combination of X-ray and SZ selections. Moreover, their masses are estimated from the Hydrostatic Equilibrium (HE) equation and all the most massive clusters in their sample are highly unrelaxed objects. While generally we expect the HE mass to be lower than the true mass, the HE mass may actually overestimate the true mass when it is obtained from extrapolation of NFW profile fitted to data in the central region (see Figure 5 of [Rasia et al. 2006](#)). [Lovisari et al. \(2020\)](#) also compared hydrostatic masses to the *Planck* masses. They compared the hydrostatic masses of 117 clusters from the ESZ sample with their *Planck* PSZ2 derived masses, finding a small offset (i.e. 4%) when the enclosed hydrostatic masses were computed at R_{500} as determined by *Planck*.

6. CONCLUSIONS

Using *Chandra* observations, we derived the Y_X proxy and associated mass for of 147 clusters with $z \leq 0.35$ from the *Planck* Early Sunyaev-Zel'dovich catalog and for 80 clusters with $z \leq 0.30$ from an X-ray flux-limited sample. The *Chandra* ESZ follow-up is complete within the *Planck* cosmological mask region. We re-extracted the *Planck* Y_{SZ} measurements centered on the more precise X-ray position and within the X-ray characteristic size (R_{500}) from the full *Planck* mission maps. This re-extraction of the SZ signal for clusters originally detected in the 10-month maps minimizes the Malmquist bias, with the residual bias due to statistical scatter being negligible.

We discuss the results in terms of two Y_{SZ} measurements: the apparent flux Y_{SZ} in units of arcmin^2 , and the intrinsic Compton parameter $D_A^2 Y_{SZ}$ in units of Mpc^2 . Our conclusions are as follows:

- The $D_A^2 Y_{SZ}-Y_X$ relation is consistent in slope with that derived by the *Planck* Collaboration from *XMM-Newton* data, with $B = 0.96 \pm 0.03$. There is a slight offset in normalisation of $(6.5 \pm 0.1)\%$ compared to the *Planck* results, which we showed is consistent with known calibration systematic uncertainties between *XMM-Newton* and *Chandra*. The resulting Y_{SZ}/Y_X ratio is 0.88 ± 0.02 , in good agreement with X-ray expectations given radially-decreasing temperature profiles, and with previous determinations. It also suggests that there is a low level of gas clumping within R_{500} . This result is independent of any mass calibration and scaling relations.
- We compared the *Chandra* X-ray masses, derived from the Y_X proxy, to the *Planck* SZ masses, derived from the $D_A^2 Y_{SZ}$ proxy. The *Planck* masses are about 10% smaller. The median ratio of $M_{500}^{SZ}/M_{500}^{Y_X} = 0.91 \pm 0.01$, is consistent with the aforementioned calibration

differences. The slope of the relation, 0.93 ± 0.03 , differs from unity at slightly more than the 2σ level. The use of the re-extracted masses does not change the $M_{500}^{SZ} - M_{500}^{YX}$ relation, but results in a significant reduction in the scatter (by a factor of two).

- The slope of the $Y_{SZ} - D_A^{-2} Y_X$ flux relation, at $B = 0.89 \pm 0.01$, is significantly less than unity. We showed that this effect is not due to measurement issues. We performed extensive simulations, involving injection of simulated clusters into *Planck* maps, and subsequent detection and re-extraction using the *Planck* SZ detection algorithm MMF3. Using these simulations, we showed that this result is not due to selection effects, intrinsic scatter, or covariance between quantities. The X-ray selected sample follows the general trend exhibited by the SZ-selected sample, and extends it down to lower SZ fluxes.
- We showed analytically that changing the $Y_{SZ} - Y_X$ relation from apparent flux (in units of arcmin^2) to intrinsic properties (in units of Mpc^2) results in a best-fit slope that is closer to unity, as observed (0.96 ± 0.03), and increases the dispersion about the relation. The redistribution resulting from this transformation implies that the best-fit parameters and dispersion of the intrinsic $D_A^2 Y_{SZ} - Y_X$ relation, and by extension the $M_{500}^{SZ} - M_{500}^{YX}$ relation derived from these quantities, will be sample-dependent.

By itself, our study cannot estimate the absolute value of any bias between the *Planck* mass and the true mass, or exclude any mass dependence of this bias. Such a mass dependence has been suggested by several lensing studies (von der Linden et al. 2014; Hoekstra et al. 2015) although the latest compilation study by Sereno & Ettori (2017) suggests

that the apparent mass dependent bias is actually due to an underlying redshift dependence. All these works are based on sub-samples of *Planck* clusters, with no simple selection criteria, so that selection effects are potentially complex. To make further progress in this field, we require a complete follow-up of a well-characterised *Planck* cluster sample with mass estimation using various techniques (X-ray proxies, HE mass, lensing masses). Such data will be available through the CHEX-MATE programme (The CHEX-MATE Collaboration 2020).

APPENDIX

A. SAMPLE SELECTION BIAS, SCATTER, AND COVARIANCE TESTS

A.1. Simulations

The present clusters were selected from the ESZ catalog, produced from detections on the *Planck* 10-month maps, while their PSZ2 Y_{SZ} flux values were extracted from the full mission maps. To quantify any possible residual bias due to the sample selection, we undertook an extensive series of simulations by generating mock ESZ and PSZ2 catalogs.

Starting from a Tinker mass function (Tinker et al. 2008), simulated clusters were injected into the *Planck* SZ ‘cosmological’ mask region (excluding the Galactic plane and the Magellanic clouds) of the 10-month maps used for the original ESZ catalog construction. Each simulated object was modeled with the Arnaud et al. (2010) pressure profile. The Y_{SZ} value corresponding to the cluster redshift and mass was drawn from the $D_A^2 Y_{SZ} - M_{500}$ relation, with a bias between the X-ray calibrated mass and the true mass, $(1 - b) = 0.65$, tuned to recover the cluster number counts for the *Planck* cosmology.

For the Y_X value, we considered Y_X physical quantities normalised by the c^* factor given by Eq. 14, i.e. expressed in same units as the intrinsic Compton parameter. We note that any selection effect will not depend on the mean ratio between the true Y_X and $D_A^2 Y_{SZ}$ value. The slope of the $D_A^2 Y_{SZ} - Y_X$ relation is expected to be close to unity, and we are interested in possible slope biases induced by selection and measurements. For simplicity, we thus assume that the normalisation and slope of the $Y_X - M_{500}$ and $D_A^2 Y_{SZ} - M_{500}$ scaling relations are the same.

However, we allow for different scatters and a possible covariance between Y_X and $D_A^2 Y_{SZ}$ variations from the relation. We can thus write:

$$Y_M = AE(z)^{2/3} M^B$$

$$P(D_A^2 Y_{SZ}, Y_X | Y_M) = \mathcal{N}(Y_M, V_\sigma) \quad (\text{A1})$$

where Y_M is the latent Y value at a given mass (i.e. the values of Y_X and $D_A^2 Y_{SZ}$ obtained if there were no scatter), and $D_A^2 Y_{SZ}$ and Y_X are the true values. We assume a Gaussian log-normal correlated distribution for Y_{SZ} and Y_X at fixed mass, $\mathcal{N}(Y_M, V_\sigma)$, with a covariance matrix, V_σ :

$$\begin{pmatrix} \sigma_{\log, Y_{SZ}}^2 & r \sigma_{\log, Y_{SZ}} \sigma_{\log, Y_X} \\ r \sigma_{\log, Y_{SZ}} \sigma_{\log, Y_X} & \sigma_{\log, Y_X}^2 \end{pmatrix}$$

where $\sigma_{\log, Y_{SZ}}$ and σ_{\log, Y_X} are the scatter in the log–log plane of the Compton parameter and Y_X at fixed mass, respectively. The intrinsic Y_X and $D_A^2 Y_{SZ}$ quantities were converted to flux

using the angular distance to each cluster. In the absence of bias, the *observed* $Y_{SZ} - D_A^{-2} Y_X$ relation should be the identity, i.e. have a slope and normalisation equal to unity. In the above, all quantities refer to values computed within a sphere of radius R_{500} .

SZ detections were then obtained by applying the MMF algorithm (Melin et al. 2006) to the 10-month maps. The mock ESZ catalogs were constructed from application of a $S/N > 6$ threshold to these detections. These mock ESZ clusters were then re-injected into the full mission maps. The MMF algorithm was then run on these full mission maps, and the mock PSZ2 value at the ‘true’ position was extracted for the mock ESZ clusters. We extracted both the mock PSZ2 value at the ‘true’ size and at the X-ray size. The measurement errors are estimated from the maps as described in Melin et al. (2006). The simulations are therefore fully representative of the observations. We ran 10 ESZ simulations, yielding a total number of 1657 clusters, allowing a very precise estimate of any bias on the slope (the precision is better than $\sim 0.5\%$). For simplicity we assume that the statistical errors on Y_X are negligible.

In the following, we detail a step-by-step analysis of the simulated relations and the inter-dependence of Malmquist bias, intrinsic scatter, and covariance between the quantities. We focus on the $Y_{SZ} - D_A^{-2} Y_X$ relation between the SZ flux and its X-ray equivalent. This is the most fundamental observed relation, on which selection effects are expected to be most visible (particularly at the low end). The left-hand panel of Fig. 9 shows the effect of Malmquist bias on the observed Y_{SZ} values as compared to the latent $D_A^{-2} Y_M$ value, while the other panels show the corresponding $Y_{SZ} - D_A^{-2} Y_X$ relation and the effect of Y_X intrinsic scatter and covariance with $D_A^2 Y_{SZ}$. Unless otherwise stated the fit results are obtained with the BCES method.

 A.1.1. Malmquist bias due to Planck noise and intrinsic scatter in the $D_A^2 Y_{SZ} - M_{500}$ relation

We first assume that there is no intrinsic scatter in the $D_A^2 Y_{SZ} - M_{500}$ relation. The corresponding observed Y_{SZ} value, extracted at the true size, is shown in the top-left panel of Fig. 9 as a function of $D_A^{-2} Y_M$. The scatter in the y-axis direction is entirely due the observational uncertainties in the SZ measurements. Object selection was performed on the 10-month (ESZ) map and the Y_{SZ} signal is extracted from the full (29-month) mission maps. The noise between the ESZ and PSZ2 maps is slightly correlated, so we estimate here the residual effect of the ESZ selection on the flux estimation in the PSZ2 map. The effect on the slope is very small (slope 0.994 ± 0.003), implying a negligible impact.

Figure 9. Simulated Y_{SZ} re-extracted from PSZ2 maps, as a function of $D_A^{-2}Y_M$ (left columns) and $D_A^{-2}Y_X$ (other columns), for various assumptions on scatter and co-variance. Y_M is the Compton parameter corresponding to the cluster mass for the mean $D_A^2 Y_{SZ}-M_{500}$ relation, i.e. the value that would be obtained if there was no scatter in the relation. The scatter in $D_A^2 Y_{SZ}$ and Y_X at fixed mass, $\sigma_{\log,Y_{SZ}}$ and σ_{\log,Y_X} , respectively, are indicated in each panel. *Middle panels:* There is no correlation between Y_{SZ} and Y_X deviations. *Bottom right:* There is covariance with $r = 0.4$ (Eq. A.1). The different cases are discussed in the text.

We now include intrinsic scatter in the $D_A^2 Y_{SZ}-M_{500}$ relation, assuming $\sigma_{\log Y_{SZ}} = 0.05$ (Kay et al. 2012; Le Brun et al. 2017). Addition of intrinsic scatter increases the dispersion in the Y-direction, and has the effect of changing the sample selection. The resulting relation is shown in the bottom-left panel of Fig. 9. Objects that are newly-detected as compared to the previous case (about 10%) are plotted in red, and objects that are lost (no longer detected) are plotted in green (7%). As expected, lost objects are on average less intrinsically bright than newly-detected objects, specially at low flux, as more up-scattered systems pass the threshold than down-scattered systems. The intrinsic scatter then pushes the slope slightly away from unity, to 0.98 ± 0.005 (a 2% effect). This is however still far from the observed value 0.89 ± 0.01 .

A.1.2. Using the Y_X proxy and the Eddington bias

We now consider $D_A^{-2}Y_X$ as the covariate, the observable we consider in this study. We assumed $\sigma_{\log,Y_X} = 0.07$ following numerical simulations (Planelles et al. 2014; Le Brun et al. 2017; Truong et al. 2018). The corresponding $Y_{SZ}-D_A^{-2}Y_X$ relations are shown in the middle panel of Fig. 9, for the two cases described in the previous Section. Y_X is a scattered

estimate of Y_M , so the effect is to introduce scatter in the X-axis direction. The extraction at the X-ray size rather than at the ‘true’ size changes slightly the Y_{SZ} value, but the effect is very small. We also note that the slope is decreased, as compared to that of the $Y_{SZ}-Y_M$ relation, by about $\Delta B = -0.02$, with a slope of 0.972 ± 0.005 , for $\sigma_{\log,Y_{SZ}} = 0$, and 0.962 ± 0.006 for $\sigma_{\log,Y_{SZ}} = 0.05$, respectively.

This slope decrease is reminiscent of the Eddington-like bias, as described extensively by Sereno & Ettori (2015). This bias is due to the intrinsic scatter of the covariate, (here Y_X) with respect to the latent quantity (Y_M) when it has a non-uniform distribution. However this does not fully explain the effect, which we fail to fully understand. Indeed, the same slope is found using the LIRA regression code, designed to correct for this effect: 0.95 ± 0.02 , for the nominal case with intrinsic scatter in Y_{SZ} . The same agreement between LIRA and BCES results was noted for the observations ((Table 3)

We next added covariance between the Y_X and Y_{SZ} deviations, assuming a correlation coefficient $r = 0.4$ (e.g. Farahi et al. 2019; Nagarajan et al. 2019). The bottom-right panel of Figure 9 shows the resulting relation, indicating that addition of covariance pushes the slope back towards unity, to

0.973 ± 0.005 . This is due to the correlation between the deviations of the quantities in the two axes. Increasing the correlation coefficient from $r = 0.4$ to $r = 0.6$ increases the push towards unity with the slope changing to 0.982 ± 0.005 . For a perfect correlation, Y_X and Y_{SZ} would simply move along the line, canceling the Malmquist bias due to intrinsic scatter.

A.1.3. *Extreme case: large value of an intrinsic scatter in the M_{500} - Y_{SZ} relation*

As a final test, we doubled the intrinsic scatter in the M_{500} - Y_{SZ} relation, so that $\sigma_{\log Y_{SZ}} = 0.10$. If $r = 0$, the increased dispersion in the Y-direction again affects the sample selection, but more strongly than in the bottom-left panel of Fig. 10, driving the slope to 0.930 ± 0.008 . However, as in the nominal case, inclusion of covariance again redresses the slope towards unity: for $r = 0.4$, the slope becomes 0.955 ± 0.007 , and for $r = 0.6$, the slope is 0.967 ± 0.006 .

The general conclusion is that biases due to selection effects and intrinsic scatter cannot explain the observed slope of the $Y_{SZ}-D_A^{-2}Y_X$ flux relation. As we used PSZ2 SZ values, largely independent of the detection values, the residual Malmquist bias is dominated by the intrinsic scatter between the $D_A^2 Y_{SZ}$ and the mass. The intrinsic scatter in Y_X is found to slightly further reduce the slope, but covariance between Y_X and $D_A^2 Y_{SZ}$ redresses the slope towards unity. For typical scatter and covariances derived from simulations, the net effect is an decrease of the slope to $B \sim 0.97$, far from the observed value of 0.89 ± 0.01 . The combination of factors that gives the most deviant slope from unity requires unrealistically large intrinsic scatter in the $D_A^2 Y_{SZ}-M_{500}$ relation and zero covariance between Y_X and $D_A^2 Y_{SZ}$, and even when doubling the $D_A^2 Y_{SZ}$ scatter the slope still does not agree with the data.

A.2. *Further tests*

We further checked that the Malmquist bias due to *Planck* noise fluctuations is indeed negligible in the data when using PSZ2 values for the ESZ clusters, by examining the correlation between the PSZ2 Y_{SZ}/Y_X ratio and the S/N of the ESZ detection. The Y_{SZ} measured in the ESZ maps is affected by Malmquist bias, as clusters with a signal that is boosted by positive noise have a higher probability to be detected, particularly close to detection threshold. The signature of this bias is a correlation between the ratio of the observed signal to the true signal, $Y_{SZ}/Y_{SZ,true}$, with the S/N of the ESZ detection. If the PSZ2 measurements were fully independent, this correlation would disappear. We do not have access to $Y_{SZ,true}$, but we can use Y_X as a proxy as it is not affected by the *Planck* noise in the SZ detection. A negligible dependence of the Y_{SZ}/Y_X ratio on S/N would imply negligible Malmquist bias due to *Planck* noise.

However, a difficulty is that more massive clusters are easier to detect, so that the S/N is correlated to mass as shown on

Table 4. Spearman rank coefficient and significance of Malmquist bias tests.

Relation	r	p	sub-sample	
			r	p
$M_{Y_X}-S/N$	0.542	9.2×10^{-13}	-0.003	0.99
$Y_{SZ}/Y_X-S/N$	-0.345	1.6×10^{-5}	-0.015	0.92
$M_{500}^{SZ}/M_{500}^X-S/N$	-0.372	3.0×10^{-6}	-0.025	0.87

NOTE—Columns list the rank coefficient and significance of Malmquist bias tests for the full and sub-samples. The null hypothesis p -value is the probability that the observed coefficient is obtained by chance if the two parameters are completely independent.

the left panel of Figure 10. To disentangle a possible intrinsic mass dependence of the Y_{SZ}/Y_X ratio from a dependence on the S/N due to the Malmquist bias, we selected a sub-sample of clusters of nearly the same mass, in a very restricted mass range of $M_{500}^{Y_X} = (8.5 \pm 1.5) \times 10^{14} M_\odot$. The mean mass of the sub-sample was chosen to maximize the S/N leverage, while ΔM is small enough to ensure that there is no residual correlation between mass and S/N . The clusters in this sub-sample are identified by red points in the left panel of Figure 10. The Y_{SZ}/Y_X for the full sample is significantly correlated with the S/N and increases at low S/N (central panel of Figure 10). However the correlation with S/N disappears for the sub-sample at a given mass range ($r = -0.015$, $p = 0.92$). The same is found for the mass ratio ($r = -0.025$, $p = 0.87$).

This test shows that the Malmquist bias due to *Planck* noise fluctuations is indeed negligible when considering PSZ2 Y_{SZ} values. Note that this does imply a negligible Malmquist bias due to intrinsic scatter of Y_{SZ} with mass. Clusters detected because their Y_{SZ} are scattered up at a given mass may have also a higher Y_X value due to covariance between Y_{SZ} and Y_X deviations at given mass, so that the ratio Y_{SZ}/Y_X remains weakly dependent on S/N .

B. TESTING A MASS DEPENDENCE ON CHANDRA-PLANCK CENTER OFFSET

The uncertainty on the *Planck* cluster center is determined by the spatial resolution of its instruments. Here, we compare the cluster centers determined by the *Planck* detection algorithm (\sim arcmins) to the precise (\sim arcsec) *Chandra* centroids. The mean offset between the *Chandra* and *Planck* centers is $1.7'$, similar to the result obtained by [Planck Collaboration IV \(2013\)](#) of $1.5'$, and in agreement with expectations from the *Planck* sky simulations ([Planck Collaboration VIII 2011](#), see their Section 6.1).

We investigate a possible dependence of the SZ to X-ray derived mass ratio (see Figure 11) on the offset between the

Figure 10. Verification of the importance of the Malmquist bias. Left panel: Correlation between M_{500}^{SZ} and the S/N of the ESZ detection. Red points corresponds to the sub-sample used to check for the Malquist bias effect, effectively removing the intrinsic mass dependence from the S/N of the detection (see text). Center and Right panel: correlation between the SZ and mass ratio as a function of S/N . The correlations coefficients for the full sample and sub-sample are given in the plots and Table 4.

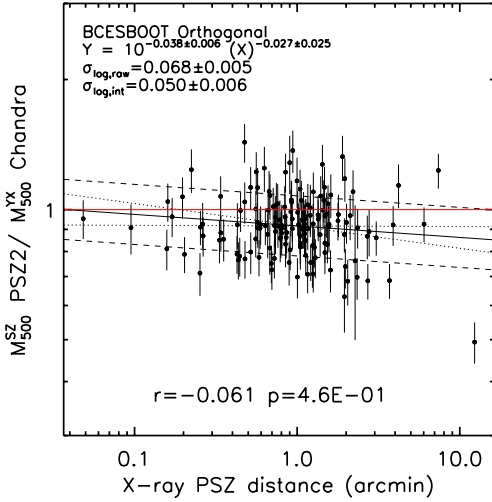

Figure 11. Ratio between SZ and X-ray derived masses plotted against the projected distances between the cluster centers as measured using *Planck* and *Chandra* data. The solid black line corresponds to the power-law best fit, while the solid red line corresponds to equal SZ and X-ray derived masses. The dashed line corresponds to the 1σ confidence range. The dotted line corresponds to the 1σ envelope on the best-fitting line.

Planck and *Chandra* centers. The relation between the SZ to X-ray derived mass ratio and the offset between the *Planck* and *Chandra* positions (ΔR) is given by:

$$M_{500}^{SZ}/M_{500}^{YX} = 10^A \times \Delta R^B. \quad (\text{B2})$$

Our results are presented in Table 5. We find no evidence of a correlation between the two quantities (under the null hypothesis of no correlation, we obtained a p -value of 0.46), suggesting that the large *Planck* position uncertainty ($\sim 2'$) is not driving the differences in cluster mass determinations.

Table 5. Best Fit Parameters for the Ratio Between SZ and X-ray Masses

Relation	A	σ_A	B	σ_B
Ratio versus ΔR	-0.038	0.006	-0.027	0.025

NOTE—Columns list best fit parameters and their uncertainties for the power-law given by Equation (B2).

C. DIFFERENCE IN SLOPE OF THE $Y_{SZ}-Y_X$ RELATION WHEN EXPRESSED IN APPARENT FLUX (UNITS OF ARCMIN²) AND INTRINSIC PROPERTIES (UNITS OF MPC²)

As noted throughout the text, we observe a statistically significant difference in the slope of the $Y_{SZ}-Y_X$ relation when expressed in apparent flux (units of arcmin²) compared to intrinsic properties (units of Mpc²), as clearly seen also in Figure 12. When clusters are color-coded according to their gas temperatures, we clearly see on the right panel of Figure 12 that clusters are ordered by color, as expected when the $Y_{SZ}-Y_X$ relation is expressed in intrinsic properties (units of Mpc²). On the other hand, on the left panel of the Figure 12 the colors are more evenly spread throughout the $Y_{SZ}-Y_X$ relation. A re-ordering of data points occurs when the $Y_{SZ}-Y_X$ relation is expressed in intrinsic properties instead of apparent flux because this change depends on the underlying cosmology and cluster redshift, the result being a different multiplying factor for each cluster. In this Appendix we show that this change from apparent flux to intrinsic properties results in a best-fit $Y_{SZ}-Y_X$ relation slope that is closer to unity when expressed in intrinsic properties (units of Mpc²).

Figure 12. Observed change in slope in the $Y_{SZ}-Y_X$ relation caused by the change from apparent flux to intrinsic properties. The points are color-coded according to the values of the gas temperature. As we can see, despite being separated in the $Y_{SZ}-Y_X$ relation in intrinsic properties (units of Mpc^2), the colors are mixed when the same relation is expressed in apparent flux (units of arcmin^2), illustrating the redistribution that happens when the $Y_{SZ}-Y_X$ relation is expressed different physical quantities. This redistribution ultimately changes the slope of the $Y_{SZ}-Y_X$ relation. Left: the best fit relation is given by $Y_{SZ} \propto (Y_X)^{0.89}$ in apparent flux (units of arcmin^2). Right: same as top left panel, except for $Y_{SZ} \propto (Y_X)^{0.96}$ in intrinsic properties (units of Mpc^2).

C.1. Analytical demonstration of the change in slope and dispersion

For simplicity, the linear regression presented here is undertaken using the least squares method. For n pairs of data (x, y) , the method of least squares may be used to write a linear relationship between x and y . The least squares regression line is the locus that minimizes the sum of the squares of the vertical deviation from each data point from the best fit linear relation.

The least square regression line for a set of n data points is given by the equation of a line:

$$y = a + bx, \quad (\text{C3})$$

where a , b , and the variance, σ^2 , about the best fit are given by $(\sum_{i=1}^n \rightarrow \Sigma)$:

$$b = \frac{n \sum x_i y_i - (\sum x_i) (\sum y_i)}{n \sum x_i^2 - (\sum x_i)^2} \quad (\text{C4})$$

$$a = \frac{\sum y_i - b \sum x_i}{n} \quad (\text{C5})$$

$$\sigma^2 = \frac{\sum (y_i - a - bx_i)^2}{n - 1}. \quad (\text{C6})$$

Assuming that the data are now best described by a power-law relation given by $y = ax^b$, one can linearize this relation by applying a logarithmic function to both sides of this equality:

$$\log(y) = \log(a) + b \log(x) \rightarrow z = a_0 + a_1 w. \quad (\text{C7})$$

Now, let us perform the following linear transformation on the data (x, y) :

$$y' = \zeta y : y'_i = \zeta_i y_i \text{ and } x' = \zeta x : x'_i = \zeta_i x_i, \quad (\text{C8})$$

where the coefficient ζ_i is unique for each pair of data (x_i, y_i) . If each data point (x_i, y_i) has a dispersion about the best fit relation given by $1 + \epsilon_i$, such that $y_i = ax_i^b(1 + \epsilon_i)$, the linear transformation leads to $y'_i = a\zeta_i x_i^b(1 + \epsilon_i) = a\zeta_i^{1-b} x_i^b(1 + \epsilon_i)$, which can be

linearized as:

$$\log(y'_i) = \log(a) + (1-b)\log(\zeta_i) + \log(1 + \epsilon_i) + b \log(x'_i) \rightarrow z'_i = a_0 + (1-b)a_{1,i} + a_{2,i} + bw'_i. \quad (\text{C9})$$

Using the linearized equation presented in (C9), equation (C5) takes the following form:

$$\begin{aligned} b' &= \frac{n \sum w'_i z'_i - (\sum w'_i)(\sum z'_i)}{n \sum w'^2_i - (\sum w'_i)^2} \\ &= \frac{n \sum (a_0 w'_i + (1-b)a_{1,i} w'_i + a_{2,i} w'_i + b w'^2_i) - (\sum w'_i)(\sum (a_0 + (1-b)a_{1,i} + a_{2,i} + b w'_i))}{n \sum w'^2_i - (\sum w'_i)^2} \\ &= \frac{n \sum a_0 w'_i + n \sum (1-b)a_{1,i} w'_i + n \sum a_{2,i} w'_i + n \sum b w'^2_i - n \sum a_0 w'_i - \sum (1-b)a_{1,i} \sum w'_i - \sum a_{2,i} \sum w'_i - b (\sum w'_i)^2}{n \sum w'^2_i - (\sum w'_i)^2} \\ &= b + (1-b) \frac{n \sum a_{1,i} w'_i - \sum a_{1,i} \sum w'_i}{n \sum w'^2_i - (\sum w'_i)^2} + \frac{n \sum a_{2,i} w'_i - \sum a_{2,i} \sum w'_i}{n \sum w'^2_i - (\sum w'_i)^2}, \end{aligned} \quad (\text{C10})$$

Figure 13. Visualization of the ζ - ζx relation in logarithmic space. Top left: illustration of boundaries for the pairs $(\zeta_i, \zeta_i x_i)$ when $\zeta_i \in [\zeta_{\text{inf}}, \zeta_{\text{sup}}]$ and $x_i \in [x_{\text{inf}}, x_{\text{sup}}]$. Top right: illustration of the slope of the best power-law fit when $x_{\text{inf}} \sim x_{\text{sup}}$ and $\zeta_{\text{inf}} \ll \zeta_{\text{sup}}$. Bottom left: same as top right panel, except for $x_{\text{inf}} \ll x_{\text{sup}}$ and $\zeta_{\text{inf}} \sim \zeta_{\text{sup}}$. Bottom right: same as top right panel, except for $x_{\text{inf}}/x_{\text{sup}} = \zeta_{\text{inf}}/\zeta_{\text{sup}}$.

Figure 14. Toy model of the change in slope caused by the change of units from arcmin² to Mpc². The points are color-coded according to the mock values of Y_X in units of Mpc², which should be closely related to a temperature dependence. As we can see, despite being separated in the $Y_{SZ}-Y_X$ relation in units of Mpc², the colors are mixed when the same relation is plotted in units of arcmin², illustrating the re-distribution that happens when the values are presented in other units. This re-distribution ultimately changes the slope of the best fit, in this particular set of examples as given by $b' = b + (1 - b)/2$. Top left: creating a distribution that follows $Y_{SZ} \propto (Y_X)^1$ in units of arcmin², one gets the same slope in units of Mpc², as expected from $b' = b + (1 - b)/2$. Top right: same as top left panel, except for $Y_{SZ} \propto (Y_X)^{0.90}$ in units of arcmin² leading to $Y_{SZ} \propto (Y_X)^{0.95}$ in units of Mpc². Bottom left: same as top left panel, except for $Y_{SZ} \propto (Y_X)^{0.80}$ in units of arcmin² leading to $Y_{SZ} \propto (Y_X)^{0.90}$ in units of Mpc². Bottom right: same as top left panel, except for $Y_{SZ} \propto (Y_X)^{0.70}$ in units of arcmin² leading to $Y_{SZ} \propto (Y_X)^{0.86}$ in units of Mpc².

which becomes

$$b' = b + (1 - b) \frac{n \sum \log(\zeta_i) \log(\zeta_i x_i) - \sum \log(\zeta_i) \sum \log(\zeta_i x_i)}{n \sum \log(\zeta_i x_i)^2 - (\sum \log(\zeta_i x_i))^2} + \frac{n \sum \log(1 + \epsilon_i) \log(\zeta_i x_i) - \sum \log(1 + \epsilon_i) \sum \log(\zeta_i x_i)}{n \sum \log(\zeta_i x_i)^2 - (\sum \log(\zeta_i x_i))^2}, \quad (C11)$$

where the term multiplying $(1 - b)$ is the slope of the best fit of $\zeta(x') \equiv \zeta(\zeta x)$ in logarithmic space (compare Equation (C12) with (C4)), which will be named β . The last term is the slope of the best fit of the $(1 + \epsilon) - \zeta x$ relation in logarithmic space. Assuming there is no correlation between the dispersion about the original best fit relation and the transformed x-coordinate (ζx), the last term of Equation (C11) vanishes, so that it finally becomes:

$$b' = b + (1 - b) \frac{n \sum \log(\zeta_i) \log(\zeta_i x_i) - \sum \log(\zeta_i) \sum \log(\zeta_i x_i)}{n \sum \log(\zeta_i x_i)^2 - (\sum \log(\zeta_i x_i))^2}. \quad (\text{C12})$$

Following the same arguments, we can also express (for completeness) the new linear coefficient a' as:

$$a' = \log(a) + (1 - b) \frac{\sum \log(\zeta_i) - \beta \sum \log(\zeta_i x_i)}{n}, \quad (\text{C13})$$

where the term multiplying $(1 - b)$ is the linear coefficient of the best fit of $\zeta(x') \equiv \zeta(\zeta x)$ in logarithmic space (compare Equation (C13) with (C5)), which will be named α .

We can finally express the new dispersion σ' , following again steps similar to those leading to Equation (C12), by:

$$\sigma'^2 = \frac{\sum \log(1 + \epsilon_i)^2}{n - 1} + (1 - b)^2 \frac{\sum (\log(\zeta_i) - \alpha - \beta \log(\zeta_i x_i))^2}{n - 1}, \quad (\text{C14})$$

where the first term is the variance of the starting relation, σ^2 , the term multiplying $(1 - b)^2$ is the variance of $\zeta(x') \equiv \zeta(\zeta x)$ with respect to its best fit in logarithmic space (compare Equation (C14) with (C6)), which will be named γ^2 .

We can now express Equations (C12), (C13), and (C14) simply as:

$$\begin{aligned} a' &= \log(a) + \alpha (1 - b), \\ b' &= b + \beta (1 - b), \\ \sigma'^2 &= \sigma^2 + \gamma^2 (1 - b)^2. \end{aligned} \quad (\text{C15})$$

From Figure 13, we can easily see that $0 \leq \beta \leq 1$. This inequality, in conjunction with the set of Equations (C15), leads to the immediate conclusion that for $b \neq 1$ the linear transformation we have just presented will result in a best-fit relation that is closer to unity, while increasing the dispersion of the data around this best-fit.

Now let us assume that both ζ and x are random variables uniformly distributed in the intervals $[\zeta_{\text{inf}}, \zeta_{\text{sup}}]$ and $[x_{\text{inf}}, x_{\text{sup}}]$ (see top left panel of Figure 13). If $x_{\text{inf}} \sim x_{\text{sup}}$ and $\zeta_{\text{inf}} \ll \zeta_{\text{sup}}$, the slope of the best fit of $\zeta(\zeta x)$ is ~ 1 (see top right panel of Figure 13), and Equation (C12) becomes $b' \cong 1$. If $x_{\text{inf}} \ll x_{\text{sup}}$ and $\zeta_{\text{inf}} \sim \zeta_{\text{sup}}$, the slope of the best fit of $\zeta(\zeta x)$ is ~ 0 (see bottom left panel of Figure 13), and Equation (C12) becomes $b' \cong b$. If $x_{\text{inf}}/x_{\text{sup}} = \zeta_{\text{inf}}/\zeta_{\text{sup}}$, the slope of the best fit of $\zeta(\zeta x)$ is $1/2$ (see bottom right panel of Figure 13), and Equation (C12) becomes $b' = b + (1 - b)/2$, which means that after random distributions of x and y (with the same factor, ζ_i , multiplying both coordinates for each data point) the best fit slope is closer to unity, decreasing the difference by half. To test this analytical prediction we created mock representations of the $Y_{\text{SZ}}-Y_{\text{X}}$ relation, which are presented in the next section.

C.2. Mock representations of the $Y_{\text{SZ}}-Y_{\text{X}}$ relation

To test the analytical prediction presented in the previous section, we created mock representations of the $Y_{\text{SZ}}-Y_{\text{X}}$ relation, using 200 data points. Initially, we populated the $Y_{\text{SZ}}-Y_{\text{X}}$ relation with values in a similar range as presented in Figure 12 to mimic the $Y_{\text{SZ}}-Y_{\text{X}}$ relation when expressed in apparent flux (units of arcmin²). We then randomly re-distributed the data points using a random variable uniformly distributed in the $[0, 0.1]$ range to mimic the values presented in the $Y_{\text{SZ}}-Y_{\text{X}}$ relation when expressed in intrinsic properties (units of Mpc²). The mock representations of the $Y_{\text{SZ}}-Y_{\text{X}}$ relation are presented in Figure 14. As we can see, the best-fit results agree perfectly with the analytical prediction ($b' = b + (1 - b)/2$) presented in Section C.1 (see Table 6).

Table 6. Best Fit Slope for the $Y_{\text{SZ}}-Y_{\text{X}}$ expressed in apparent flux (units of arcmin²) and intrinsic properties (Mpc²) for our Mock Relations

B_{arcmin^2}	$\sigma_{B_{\text{arcmin}^2}}$	B_{Mpc^2}	$\sigma_{B_{\text{Mpc}^2}}$	Predicted
1.00	0.01	1.00	0.01	1.00
0.90	0.01	0.95	0.01	0.95
0.80	0.01	0.90	0.01	0.90
0.70	0.01	0.86	0.02	0.85

NOTE—Columns list best fit slopes and their uncertainties for the power-law fit to the $Y_{\text{SZ}}-Y_{\text{X}}$ relation expressed in apparent flux (units of arcmin²), intrinsic properties (units of Mpc²), and the predicted value given by $B_{\text{Mpc}^2} = B_{\text{arcmin}^2} + (1 - B_{\text{arcmin}^2})/2$.

C.3. Predicted vs. observed change in slope for our sample

Finally, we investigate the predicted change in slope for our sample, using the factors (ζ_i) that were used for the conversion from apparent flux (units of arcmin²) to intrinsic properties (units of Mpc²). Using the notation of Section C.1 and starting from the $Y_{SZ}-Y_X$ relation expressed in apparent flux (units of arcmin²), we have:

- $x_i = Y_{X,\text{arcmin}^2}^i$ and $y_i = Y_{SZ,\text{arcmin}^2}^i$;
- $\zeta_i = Y_{SZ,\text{Mpc}^2}^i / Y_{SZ,\text{arcmin}^2}^i = Y_{X,\text{Mpc}^2}^i / Y_{X,\text{arcmin}^2}^i$ and $\zeta_i x_i = Y_{X,\text{Mpc}^2}^i$;
- b = slope of the best fit of the $Y_{SZ}-Y_X$ relation in apparent flux (units of arcmin²) and b' = slope of the best fit of the $Y_{SZ}-Y_X$ relation in intrinsic properties (units of Mpc²).

Using the formalism presented in Section C.1 and the variables as defined above, the predicted slope of the best fit of the $Y_{SZ}-Y_X$ relation when changed from apparent flux (units of arcmin²) to intrinsic properties (units of Mpc²) is given by Equation (C12), where the term multiplying $(1 - b)$ is the slope of the best fit of the $(Y_{SZ,\text{Mpc}^2} / Y_{SZ,\text{arcmin}^2}) - Y_{X,\text{Mpc}^2}$ relation ($\zeta-\zeta x$) in logarithmic space, which turns out to be 0.85 (see bottom panel of Figure 15). This leads to a predicted slope of the best fit of the $Y_{SZ}-Y_X$ relation in intrinsic properties of $b' = 0.89 + (1 - 0.89) \times 0.85 = 0.98$, which is in agreement with the the observed value of 0.96 ± 0.03 . Now, if we perform the same calculation to compute the predicted value of the slope of the $Y_{SZ}-Y_X$ in apparent flux starting from this relation in intrinsic properties (the slope of the best fit of $\zeta-\zeta x$ is 0.90 – see bottom panel of Figure 15), we obtain: $b' = 0.96 + (1 - 0.96) \times 0.90 = 1.00$, which is in total disagreement with the observed value of 0.89 ± 0.01 .

The question that then arises naturally is why going from apparent flux to intrinsic properties results in a slope that is closer to unity, and yet the reverse is not the case.

Based on the analytical formalism presented in Section C.1, we know that any re-ordering of the data will result in a slope that is closer to unity. However, the analytical formalism does not indicate any mathematical property that allows us to know the direction that this transformation results in a slope that is closer to unity.

The answer to this question seems to be given by understanding what is first observed, therefore what is the starting point. The observed integrated Compton parameter (Y_{SZ}) is measured from the apparent flux (arcmin²) from the *Planck* data. Similarly, the X-ray equivalent of the integrated Compton parameter, Y_X , which is given by the product of a gas mass and a gas temperature, has a cosmological dependence on the gas mass, which is originally measured from the observed emission measure profile, and which is therefore also

dependent on the apparent flux. It is only after calculations involving the underlying cosmology and cluster redshift that Y_X is presented in intrinsic properties (M_⊙ keV or Mpc²). Based on this reasoning, we see that the starting point is given by measurements that involve the apparent flux. Therefore, going from apparent flux (units of arcmin²) to intrinsic properties (units of Mpc²) should result in a best-fit slope that is closer to unity according to our analytical formalism presented in Section C.1. This is indeed what we observe.

Figure 15. Top: Observed change in slope in the $Y_{SZ}-Y_X$ relation caused by the change of units from arcmin^2 to Mpc^2 . The points are color-coded according to the cluster redshift. As we can see, despite being separated in the $Y_{SZ}-Y_X$ relation in units of arcmin^2 , the colors are mixed when the same relation is plotted in units of Mpc^2 , showing a contrary effect compared to when the colors are coded according to the cluster gas temperature (when color-coded according to the gas temperature, colors are separated in units of Mpc^2 – Figure 12). This illustrates the redistribution that happens when the values are presented in different units. This redistribution ultimately changes the slope of the $Y_{SZ}-Y_X$ relation. Top left: the best fit relation is given by $Y_{SZ} \propto (Y_X)^{0.89}$ in units of arcmin^2 . Top right: same as top left panel, except for $Y_{SZ} \propto (Y_X)^{0.96}$ in units of Mpc^2 . Bottom: Observed $\zeta-\zeta x$ relation in logarithmic space for our ESZ sample. As for the top panels, the points are color-coded according to the cluster redshift. Bottom left: Observed $\zeta-\zeta x$ relation used for predicting the change of slope of the $Y_{SZ}-Y_X$ relation when units are changed from Mpc^2 to arcmin^2 . The best fit slope is given by $\beta = 0.90 \pm 0.07$. Bottom right: Same as bottom left panel, except for changing from units of arcmin^2 to Mpc^2 . The best fit slope is given by $\beta = 0.85 \pm 0.10$.
