## Abstract

**Summary** This study in 8 countries across Europe found that about 75% of elderly women seen in primary care who were at high risk of osteoporosis-related fractures were not receiving appropriate medication. Lack of osteoporosis diagnosis appeared to be an important contributing factor.

**Introduction** Treatment rates in osteoporosis are documented to be low. We wished to assess the osteoporosis treatment gap in women  $\geq 70$  years in routine primary care across Europe.

**Methods** This cross-sectional observational study in 8 European countries collected data from women 70 years or older visiting their general practitioner. The primary outcome was treatment gap: the proportion who were not receiving any osteoporosis medication among those at increased risk of fragility fracture (using history of fracture, 10-year probability of fracture above country-specific Fracture Risk Assessment Tool [FRAX] thresholds, T-score  $\leq -2.5$ ).

**Results** Median 10-year probability of fracture (without bone mineral density [BMD]) for the 3798 enrolled patients was 7.2% (hip) and 16.6% (major osteoporotic). Overall, 2077 women (55%) met one or more definitions for increased risk of fragility fracture: 1200 had a prior fracture, 1814 exceeded the FRAX threshold, and 318 had a T-score  $\leq -2.5$  (only 944 received a dual-energy x-ray absorptiometry [DXA] scan). In those at increased fracture risk, the median 10-year probability of hip and major osteoporotic fracture was 11.2% and 22.8%, vs 4.1% and 11.5% in those deemed not at risk. An osteoporosis diagnosis was recorded in 804 patients (21.2%); most (79.7%) of these were at increased fracture risk. The treatment gap was 74.6%, varying from 53% in Ireland to 91% in Germany. Patients with an osteoporosis diagnosis were found to have a lower treatment gap than those without a diagnosis, with an absolute reduction of 63%.

**Conclusions** There is a large treatment gap in women aged  $\geq 70$  years at increased risk of fragility fracture in routine primary care across Europe. The gap appears to be related to a low rate of osteoporosis diagnosis.

## Introduction

Over 8.9 million osteoporotic or fragility fractures occur every year across the globe, more than a third of which occur in Europe [1, 2]. In 2010, 3.5 million new fragility fractures (FFs) in 22 million women aged over 50 were estimated to have occurred across the EU; and FFs are predicted to increase due to changing demographics [3]. It has been suggested that approximately 51% of the hip fractures that occur globally are potentially preventable [4]. Hence, disease awareness, early diagnosis, prevention, and appropriate treatment of fractures are critical in osteoporosis (OP) management. However, the diagnosis of OP frequently occurs only after a fracture, and even then treatment rates can be low [4].

General practitioners (GPs) play a critical role in OP management. To begin with, they are well positioned to assess risk factors in the general population [5]. For example, in a cross-sectional survey on women 45 years or older in the French general population, the diagnosis of OP was most commonly made by a GP (approximately 45% of diagnoses [6]); and in a single OP clinic in the UK, 94% of the referrals for bone mineral density (BMD) scans over the course of 1 year had been made by GPs [7]. For patients who experience OP-related fractures, a cost burden is also placed on primary care. A study of UK databases reported that primary care costs increased significantly in the first 2 years after hip fracture [8]. Coordinator-based fracture liaison services for secondary prevention also usually require the GP's involvement as part of a multi-disciplinary team for treating patients and monitoring their progress [9, 10].

Diagnostic methods and fracture risk assessment have improved in recent years. However, despite new interventions to reduce fracture risk and new clinical practice guidelines, only a small fraction of eligible women receive treatment for OP, implying a high treatment gap [11]. It was estimated that 10.6 out of the 18.4 million women in the EU who exceeded the threshold risk for FF were not treated, representing a treatment gap of 57% [3]. This is likely to be an underestimate, as the analysis assumed that all OP drug usage was targeted appropriately at individuals at high risk. In the absence of recent real-world data, we designed this study to specifically focus on assessing the treatment gap in a large sample of women  $\geq 70$  years in Europe who were routinely visiting their GPs.

## Methods

### Study design

This cross-sectional, multicenter, multi-country observational study included 153 GP sites across 8 countries: Belgium, France, Germany, Ireland, Poland, Slovakia, Switzerland, and the UK. Countries were included based on regulatory

requirements and feasibility. GP offices were selected based on interest in participation as a study site, and willingness and ability to comply with the protocol and data entry conventions. Community-dwelling women 70 years or older who spontaneously visited their GP were invited to participate, and, following informed consent, completed a short self-reported questionnaire.

The primary objective was to assess the proportion of women  $\geq 70$  years who were at increased risk of FF (see following) and not receiving any OP medication. Increased risk of FF was defined by the presence of at least one of the following three base criteria:

1. History of fracture after the age of 50 (hip, spine, wrist, or other OP-related fractures)
2. Increased 10-year probability of both hip and major osteoporotic fracture (calculated using Fracture Risk Assessment Tool [FRAX] without BMD above country-specific threshold (Table S1), using an approach similar to that recommended by the National Osteoporosis Guidance Group, UK [9])
3. BMD T-score  $\leq -2.5$  for lumbar spine, total hip, or femoral neck.

Key secondary objectives included the description of patient characteristics among those at increased risk of FF or not, and a description of the types of OP medications used.

Specific osteoporosis medications were assessed in the overall population, according to fracture history and according to current or previous use (within the last 10 years). Line of treatment was assessed among current users: no previously documented osteoporosis treatment indicated first-line use, and one type of previous osteoporosis medication indicated second-line use.

Sensitivity analyses were conducted using alternative definitions of increased risk of FF based on FRAX without BMD (criterion 2) and involved increasing or decreasing the major osteoporotic fracture and hip fracture thresholds by absolute values of 5% and 2%, respectively. A further analysis examined the same threshold as in the primary analysis, but with the FRAX probabilities calculated with the inclusion of BMD, where available.

### Data collection

The following variables were collected from the patient's existing medical records: demographics (age, gender, country); weight; height; body mass index (BMI); reason for consultation; smoking status; alcohol consumption; parental history of hip fracture; fracture history; falls in the past year; any known OP diagnosis; BMD results from last dual-energy x-ray absorptiometry (DXA) scan, if available; use of glucocorticoids; comorbidities (rheumatoid arthritis [RA], diabetes,

hypertension, osteoarthritis, and chronic obstructive pulmonary disease [COPD]) and associated treatments; OP medications used within the last 10 years (selective estrogen receptor modulators [SERMs], oral bisphosphonates [BPs], parenteral BPs, strontium ranelate, parathyroid hormone [PTH], anti-receptor activator of nuclear factor kappa-B ligand [anti-RANKL]/denosumab; use of vitamin D/calcium supplements).

Questionnaires were administered at the patient's single GP visit, which asked for information on the patient's age, height, weight, alcohol intake, parental hip fracture, history of fracture after age 50, and falls in the last year. Where there were discrepancies between medical records and the questionnaires, data from medical records were used.

### Study size

No formal hypothesis was tested. A sample size of 4000 (500/country) was expected to estimate the primary outcome for each participating country with sufficient precision, assuming that 40% of women  $\geq 70$  years of age would be at increased risk of fracture and at least 50% of these would not be receiving an OP medication.

### Statistical analysis

All analyses were descriptive. No statistical inference or imputations of missing data were planned. Analyses of the primary outcome were based on the primary analysis subset, i.e., all enrolled patients who were at increased risk of FF. Where applicable, secondary analyses were done on the full analysis set (FAS), consisting of all enrolled patients. Sensitivity analyses of the primary and key secondary outcomes were performed using different definitions of increased risk of FF (described earlier).

## Results

### Description of overall study population

Data were collected between 28 March 2018 and 26 October 2018. A total of 3798 patients (median age, 77 years) were enrolled. In each country, approximately 500 patients were enrolled across 18 to 25 sites (Table 1), except for Switzerland ( $n = 205$  across 6 sites). The largest number was enrolled in France ( $n = 543$ ). The most common reason for consultation was “follow-up to known disease” (52.1%), followed by “new symptoms/complaints” (21.7%), “medication refill” (20.6%), and “other” (5.6%). The median 10-year probability of hip fracture was 7.2%, and of major osteoporotic fracture, 16.6% (both calculated without BMD; Table 1).

**Table 1** Overall patient characteristics

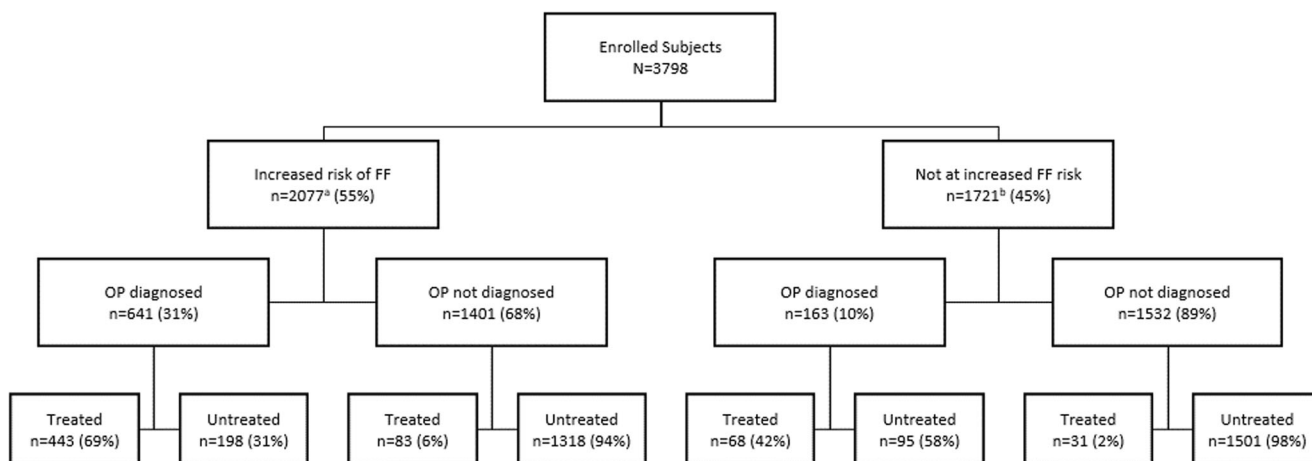

Parameter	Descriptive statistics
Country of recruitment ( <i>N</i> )	
Belgium	505
France	543
Germany	506
Ireland	500
Poland	505
Slovakia	534
Switzerland	205
UK	500
Age, median (Q1, Q3), years	77.0 (73.0, 82.0)
BMI, median (Q1, Q3), kg/m <sup>2</sup>	26.9 (23.9, 30.5)
Known OP diagnosis, <i>n</i> (%)	804 (21.2)
Reason for consultation, <i>n</i> (%)	
Follow-up to known disease	1978 (52.1)
Medication refill	782 (20.6)
New symptoms/complaints	824 (21.7)
Other	214 (5.6)
10-year fracture probability without BMD, median (Q1, Q3), %	
Hip fracture	7.2 (4.1, 11.9)
Major osteoporotic fracture	16.6 (11.5, 23.9)

*BMD*, bone mineral density; *BMI*, body mass index; *OP*, osteoporosis; *Q*, quartile

Patient recruitment and classification by fracture risk, OP diagnosis, and whether treated with OP medication or not are shown in Fig. 1. Of all the enrolled patients, 2077 (55%) were deemed to be at increased risk of FF using the base criteria for fracture risk. Of the total population, 804 patients (21.2%) had an OP diagnosis identified in their medical records, and the majority of these (641, 79.7%) were in the increased fracture risk group. Importantly, BMD results were available in 944 women only (24.9% of the cohort), with BMD results for lumbar spine available in 908 women (23.9% of the whole cohort), for the total hip in 747 women (19.6% of the whole cohort), and for the femoral neck in 727 (19.1% of the whole cohort). Thus, the number classified at high risk based on BMD (T-score  $\leq 2.5$ ) was derived from a smaller subset of the cohort.

### Prevalence of increased fracture risk and treatment gap

Those at increased risk of FF were older than those not at increased risk (median 80.0 years vs. 75.0 years; Table 2). They also had a lower median BMI and, as expected, a higher prevalence of risk factors associated with increased fracture risk apart from current smoking and alcohol exposure. Overall, 3361 patients (88.5%) reported at least one comorbidity, with similar proportions in patients with and without

**Fig. 1** Patient flowchart (adapted from [12]). FF, fragility fracture; OP, osteoporosis. <sup>a</sup>Unknown OP diagnosis in 35 patients at increased risk of fracture (1 treated, 34 untreated). <sup>b</sup>Unknown OP diagnosis in 26 patients not at increased risk of fracture (all untreated)

increased risk of FF. The most common comorbidities overall were hypertension (2840, 74.8%), osteoarthritis (1702, 44.8%), and diabetes (953, 25.1%; data not shown). The median FRAX 10-year probabilities of a major osteoporotic fracture and hip fracture (calculated without BMD) were 1.98-fold and 2.73-fold higher, respectively, than those not an increased risk (22.8 vs. 11.5 and 11.2 vs. 4.1, respectively).

For the primary outcome of treatment gap in patients at increased risk of FF, 1550 (74.6%) were not receiving OP medication (Fig. 2). Across countries, the treatment gap varied from 53% in Ireland to 91% in Germany (Online Resource Figure S1).

The treatment gap was notably different depending on whether a diagnosis of OP was recorded. Thus, in women with increased risk and a diagnosis of OP, the treatment gap was only 30.9%, while in those with increased risk and no OP diagnosis, the gap was 94.1%. A diagnosis was therefore associated with an absolute reduction in treatment gap of 63% (Fig. 2). An ad hoc analysis of the subset of patients who received a DXA scan showed that 54% (508/944) were not treated; and an analysis of the subset of patients who had a recorded T-score showed that 21% (66/318) of those with a T-score  $\leq -2.5$  were not treated.

A diagnosis of OP also influenced prescribing in those deemed not to be at increased risk of fracture (Fig. 1). Treatment was only reported in 6% of those not at increased risk, but this ranged from 2.0% in those without a diagnosis of OP to 42% in those with a diagnosis. Regardless of risk of FF, nearly all (96.1%) of those without an OP diagnosis did not receive OP medication (Fig. 1).

The reasons for being classified as being at increased risk of FF are shown in Table 3. Of the 2077 women, 1200 (57.8%) qualified because they had experienced a prior fracture. Of these, 1020 (85%) also exceeded the country-specific FRAX threshold. A further 794 women were classified because their fracture probability exceeded the country-specific

FRAX threshold. The fracture risk of these patients was similar to that observed in patients reporting a history of prior fracture (Table 3). The fracture risk in those identified by FRAX probability, whether alone or in combination with other criteria, was consistently higher than in those identified without considering fracture probability. Only a small proportion of patients met the definition for increased risk of FF by T-score only (4.0%), reflecting the fact that BMD results were only available in a small subset (24.9%) of the cohort. Of the 944 women with BMD recorded, 318 (33.7%) had a T-score of  $\leq -2.5$  at one of the 3 skeletal sites.

### OP medication use

Overall, 626 patients (16.5%) had received or were receiving OP medication, of whom 422 (67.4%) were currently using OP medication and 204 (32.6%) had used it previously. The most common OP medications used (Table 4) were oral BPs (67.4%), denosumab (29.9%), and parenteral BPs (13.6%). Patients with a history of spine fracture received an OP medication more frequently than those with a history of hip fracture (57.9% vs. 35.9%).

Oral BP constituted the majority of first-line OP medication (58.3%), followed by denosumab (28.3%) and parenteral BP (8.4%). Denosumab was the most common second-line OP medication (76.3%), followed by parenteral BP (10.0%) and oral BP (7.5%).

Most (90.1%) OP medication users also received vitamin D/calcium supplements. 30.5% of the patients overall received vitamin D/calcium supplements alone (data not shown).

### Subgroup and sensitivity analyses

Increasing or decreasing the FRAX-based thresholds (as described in the “Methods” section) only had a relatively small

BMD, bone mineral density; BMI, body mass index; FF, fragility fracture; OP, osteoporosis

<sup>a</sup> A patient will be considered to be at increased risk of fragility fracture if ≥ 1 of the 3 following criteria are met: (1) had a history of fracture; (2) 10-year probability of hip fracture without BMD > country-specific threshold and 10-year probability of major osteoporotic fracture without BMD > country-specific threshold; (3) BMD T-score ≤ − 2.5 for any of lumbar spine/total hip/femoral neck

<sup>b</sup> Number of patients enrolled in full analysis set. Percentages based on total number of patients in respective increased risk of fragility fracture category using the base definition

effect on the proportion of the population identified at increased risk. The proportion ranged from 52.3 to 57.7% for the higher and lower thresholds, respectively (Online Resource Table S2). This also had little impact on the estimates of the treatment gap, with values being 74.0% and 75.7%, respectively (Online Resource Table S3).

Since there were differences in speed of recruitment across centers, we compared the baseline characteristics of the first 50% of patients enrolled to the next 50% to see if biases had gradually influenced the types of patients recruited. Reassuringly, the characteristics were remarkably similar including age, reasons for consultation, and OP diagnosis (Online Resource Table S4), as well as for comorbidities (Online Resource Table S5) and fracture history (Online Resource Table S6).

## Discussion

Our study found a large treatment gap for women aged ≥ 70 years at increased risk of FF who were in routine primary care

across 8 countries in Europe. Overall, just over half were found to be at increased risk of FF, of whom three-quarters were not receiving any OP medication. Even among patients with prior spine or hip fractures, the treatment gap was high, with 42% and 64%, respectively, not receiving OP treatment. While the treatment gap varied, it was above 50% in all 8 countries. The treatment gap in patients with prior hip fracture was lowest in Ireland (43%), Belgium (46%), and the UK (55%), and highest in Switzerland (88%) and Germany (94%). We observed that a diagnosis of OP has a substantial impact; the treatment gap was much smaller in those with an OP diagnosis (30.9% vs. 74.6% in the overall population) and much larger in those without an OP diagnosis (94.1%). The treatment gap therefore appears to be largely related to a gap in diagnosis or awareness.

The large treatment gap reported here is consistent with previous studies. For example, treatment gaps of 55–68% have been reported for Europe using different methodologies [1, 3, 13]. Even in the presence of a prior fracture, treatment rates have been reported to be low for secondary prevention [2] and have also been shown to be declining over time [3].

**Fig. 2** OP treatment gap for overall patients and by OP diagnosis (adapted from [12]). CI, confidence interval; FF, fragility fracture; OP, osteoporosis. *N* represents the number of patients at increased risk of fragility fracture using the base definition. Thirty-five patients had an unknown diagnosis of OP

Across the EU, less than 20% of patients with FFs were reported to receive treatment within the year following fracture [1]. This treatment gap has also been reported in the elderly, for whom the consequences of untreated OP are more severe. Treatment gap was between 48 and 68% in Swedish women aged over 70, with as few as 10% of elderly women with FFs receiving any OP therapy [11]. Wide intercountry variability in treatment uptake in women with higher risk of osteoporotic fractures has also been reported in other studies [1, 3], and could be due to different availability and reimbursement of medications and differences in fracture risk. Fracture registries may play an important role in improving access to treatment: Ireland and the UK have national hip fracture registries and had a relatively low treatment gap compared with other

countries. In all of these countries, treatment guidelines suggest a case-finding approach for patient identification, but there is variation in terms of which risk factors are acknowledged, how fracture risk should be assessed, how BMD measurements should be used, and the thresholds for treatment initiation. Notwithstanding the wide availability of national guidelines, it is clear that their recommendations are not always followed.

We observed that a diagnosis of OP has a substantial impact on the treatment gap; in women at high risk, the gap was much smaller in those with an OP diagnosis than in those without (30.9% vs. 94.1%, respectively). A similarly reduced treatment gap in those with a diagnosis of OP was reported in the GLOW study [13]. A diagnosis of OP was therefore found

**Table 3** Proportion of patients at increased risk of fragility fracture and 10-year fracture probability, according to fracture risk criteria

Parameter	<i>n</i> (%)	10-year fracture probability without BMD, median (Q1, Q3), %	
		Hip fracture	Major osteoporotic fracture
Number of patients with increased risk of fragility fracture	2077 (100.0)	7.2 (4.1, 11.9)	16.6 (11.5, 23.9)
Meeting 1 of the 3 criteria			
Prior fracture only	168 (8.1)	4.4 (3.3, 5.6)	16.2 (12.7, 17.9)
FRAX threshold only	733 (35.3)	11.5 (8.9, 15.8)	21.1 (17.6, 25.8)
T-score only <sup>a</sup>	83 (4.0)	5.8 (4.1, 7.7)	13.6 (11.0, 16.5)
Meeting 2 of the 3 criteria			
Prior fracture and FRAX threshold	858 (41.3)	12.3 (8.7, 17.4)	26.7 (21.9, 32.3)
Prior fracture and T-score	12 (0.6)	5.4 (4.0, 5.9)	17.7 (16.4, 18.8)
FRAX threshold and T-score	61 (2.9)	13.9 (11.8, 18.9)	23.2 (21.1, 27.6)
Meeting all 3 criteria	162 (7.8)	14.2 (10.7, 24.0)	30.6 (25.1, 39.1)

*BMD*, bone mineral density; *FRAX*, Fracture Risk Assessment Tool; *Q*, quartile

<sup>a</sup>BMD results were only available in subset (24.9%) of the cohort

A patient was considered to be at increased risk of fragility fracture if ≥ 1 of the 3 following criteria were met: (1) had a history of fracture; (2) 10-year probability of hip fracture without BMD > country-specific threshold and 10-year probability of major osteoporotic fracture without BMD > country-specific threshold; (3) BMD T-score ≤ -2.5 for any of lumbar spine/total hip/femoral neck

Groups are mutually exclusive (i.e., patients are only counted once with respect to how they met the criteria)

Percentages based on number of patients enrolled who are at increased risk of fragility fracture using the base definition

<sup>b</sup> The proportion of patients with an individual OP treatment is expressed as a percentage of patients with any treatment in that column

to be a key factor in the decision to treat patients at increased risk of fracture. It is unclear why approximately one-third of patients with a diagnosis still remain untreated: physicians may be managing multiple other competing conditions and may consider vitamin D/calcium supplements sufficient to reduce fracture risk, or patients may have declined treatment because of confusion about the future risk of fracture compared with the risk of adverse effects, or may have developed side effects to one treatment and not transitioned to another.

Our data demonstrate that oral bisphosphonates are still the most widely used agents, comprising 58% of first-line OP medication (58.3%) compared with 28% receiving denosumab, and only 8% accessing parenteral bisphosphonate therapy. The vast majority of patients on second-line therapy received non-oral treatment (denosumab, 76%; parenteral BP, 10%), a pattern that is consistent with recommendations in key European guidelines [9, 14–16].

This study has a number of strengths as well as limitations. Care was taken during the study design and implementation to reduce bias and optimize the generalizability of the results within the participating countries. For example, site selection and assessment was conducted by a third party, to avoid inclusion of sites with an existing relationship with the sponsor and potentially having a particular interest in OP. The prevalence of risk factors and comorbidities is consistent with other studies [17–19], indicating that the current study population is representative of the primary care population. Furthermore, the consistency of patient characteristics between those recruited early to the study and those recruited later indicates that the selection criteria were not altered to fulfill enrollment targets. Our findings are consistent with a recent study in older Swedish women that showed a treatment gap of 78% in those eligible for treatment according to national guidelines [20]. Although there appears to be a clear link between osteoporosis

diagnosis and the treatment gap, the study was not designed to establish causality for factors associated with lack of treatment. We cannot exclude that a treatment decision by a GP may affect whether they enter an osteoporosis diagnosis into the medical record. Notably, the treatment gap was lowest in the subgroup of patients with a T-score  $\leq -2.5$  (21%), a finding that suggests that treatment followed the diagnosis at least in this subset of patients.

Taken together, our study and earlier studies suggest no improvement in treatment rates over the last 10 years. The increase in the treatment gap could be attributed to several factors such as misconceptions about OP, lack of perceived benefits of therapy, concern about side effects and medication costs, lack of motivation, and lack of patient education [21]. Importantly, inadequate or incorrect information in the media related to OP and its treatment are also associated with a low awareness of the disease and, subsequently, low treatment rates [22]. It is likely that novel strategies will be needed to narrow the treatment gap, particularly in older women. Greater awareness and ease of access to fracture risk assessment and treatment are likely to play a part; for example, the establishment of fracture liaison services in primary or secondary care settings increases BMD uptake and treatment exposure and is associated with reductions in fracture risk [23]. The application of fracture risk assessment in primary care and community settings was the focus of three recent randomized controlled trials of screening using the FRAX tool [17, 24, 25]. A meta-analysis of the three studies [26] showed a statistically significant reduction of major osteoporotic fractures (hazard ratio [HR] = 0.91; 95% CI = 0.84–0.98) and hip fractures (HR = 0.80; 95% CI = 0.71–0.91). The number needed to be treated to prevent one fracture was 25–28 patients. Educational and information technology-based solutions that could further facilitate fracture risk assessment in primary care could therefore be a critical step; it is of interest that there is a

negative correlation between frequency of FRAX usage in the 8 countries studied (derived from [27] and the observed treatment gap ( $r = -0.74$ , data not shown)), though this is not evidence of causation.

In conclusion, our study provides insight into the treatment gap and treatment practices in women  $\geq 70$  years of age in the primary care setting in Europe. Improved identification and assessment of fracture risk by primary care physicians should be a priority for medical bodies and policymakers, to enable informed treatment decisions that target those at greatest risk of fracture, and who are most likely to benefit from OP medications.
