ABSTRACT

We describe a first Dutch case of Hb M Saskatoon (HBB:c.190C > T p.His64Tyr) in a 47-year-old female Dutch patient who presented with cyanosis, hemolysis, and abnormal co-oximetry. A mean corpuscular volume (MCV) of 105 fL caused by reticulocytosis (160×10^9/L) and low red blood cell count (3.6×10^{12}/L) suggested an increased erythrocyte turnover. An HPLC glyco-globin analysis revealed a decreased HbA1c fraction of 12.3 mmol/mmol, HbA0 of 93.3% and an additional unidentified fraction at 1.2 min. DNA sequencing revealed a missense mutation in the *HBB* gene, (HBB:c.190C > T p.His64Tyr), known as Hb M Saskatoon, a variant which has been previously identified as an unstable hemoglobin variant leading to methemoglobinemia and anemia. In this report, we describe the clinical and remarkable laboratory aspects of our patient with Hb M Saskatoon, and the consequences for treatment and drug use.

KEYWORDS

Hb variant; Hb M Saskatoon; methemoglobin; co-oximetry; anemia; cyanosis; hemoglobin; hemoglobinopathy

Introduction

Human hemoglobin A (HbA) is a tetrameric protein consisting of two α-globins and two β-globins with noncovalently bound heme groups. Hemoglobinopathies are a group of genetic disorders resulting in quantitative or qualitative changes, leading to thalassemias or Hb-variants, respectively. Variants of the hemoglobin molecule may lead for example to altered functionality such as altered oxygen affinity, decreased stability, leading to thalassemia or chronic hemolysis in the case of hyper unstable Hb variants or methemoglobinemia. In case of the latter, the hemoglobin molecule is unable to bind oxygen due to the oxidized state of the iron ion in the heme molecule [1,2].

Clinical presentation and laboratory results

A 46-year-old Caucasian female patient with a medical history of psoriatic arthritis and irritable-bowel syndrome presented at the department of internal medicine of our hospital with a 3-month history of a debilitating fatigue and slowly progressive dyspnea on exertion. Vital signs were unremarkable although at home she had measured a saturation of 60% SpO2 on her pulse-oximeter. Physical examination revealed a distinct peripheral and central cyanosis which has been a pre-existent condition since her childhood (Figure 1). She indicated that her father had experienced similar symptoms throughout his life. He had told her that he had been diagnosed with a hemoglobinopathy, but no medical information was available. Results of the laboratory analysis are summarized in Table 1. The analysis indicated macrocytosis, increased erythrocyte turnover and decreased HbA1c of 12.3 mmol/mol with a normal fraction of HbA0 (93.3%). A microscopic analysis of the red blood cell morphology showed no aberrations. The hemoglobin separation using a Tosoh HLC-723 G8 Glycohemoglobin Analyzer (Tosoh Bioscience, Inc., South San Francisco, CA) demonstrated an unidentified Hb fraction with an approximate retention time 1.15 min (Figure 2, red arrow) that could be attributed to an unstable Hb variant. Sanger sequencing for *HBA1*, *HBA2,* and *HBB* was performed using the Big Dye Terminator kit v3.1 cycle sequencing (Applied Biosystems Inc., Foster City, CA, USA) and analysis was done on the ABI3730 according to the manufacturer's instructions. The primers and conditions for amplification and sequencing of the *HBA1, HBA2* and *HBB* gene were as described previously [3]. The sequence analysis revealed heterozygosity for a variant in the *HBB* gene: HBB: c.190C > T, p.His64Tyr. In this variant, the histidine residue 64 of the beta-globin chain distal to the porphyrin cofactor has been substituted by a tyrosine, previously annotated as Hb M Saskatoon [4]. This Hb variant has previously been described as biochemically unstable and prone to disintegration into dimers. In

Figure 1. Patient presentation. Noticeable are the cyanotic features in her extremities as well as distinct cyanotic discoloration of her lips.

other case reports, a similar small peak in the chromatogram has been observed and assigned to methemoglobin [5,6].

The genetic variant of Hb M Saskatoon was first reported in 1950 by Baltzan *et al.* and was found in a Canadian patient living in Saskatoon [4]. Over decades, patients were identified with similar clinical symptoms and abnormal hemoglobin variants. As sequencing was not yet available for most of the last century, a number of hemoglobin variants were named after the geographical area or place of residence of the patient the variant was discovered in, but later turned out to be identical to Hb M Saskatoon. A summary of Hb M Saskatoon cases is shown in Table 2.

Hb M Saskatoon is a pathogenic variant leading to methemoglobinemia. Under physiological circumstances, a Fe^{2+} ion is embedded in a porphyrin covalently bound to the α- and β-globin chains of the hemoglobin protein, where it is able to bind to an oxygen molecule. Structural changes in the Hb M variants have the effect of stabilizing the heme iron atoms in the ferric (Fe^{3+}) state, which makes the heme incapable of binding oxygen. In Hb M Saskatoon the mutation of histidine by a tyrosine residue compromises the hydrophobicity of the heme pocket and allows oxidation of the Fe^{2+} to the ferric (Fe^{3+}) state, causing methemoglobinemia.

Due to the cyanotic appearance and indication of low oxygen saturation by a portable finger pulse-oximeter (Beurer), methemoglobin analysis was performed. The blood gas analyser (Siemens Rapidpoint500) indicated abnormal spectral absorbance and issued a warning for methemoglobin. Quantitation of methemoglobin could not be performed. Co-oximetry analysis was also performed using a second blood gas analyser (Radiometer ABL90 Flex Plus). This instrument also could not detect oxygen saturation or methemoglobin values, because of interference attributed to the presence of unstable methemoglobinemia. In a previous case of a patient carrying the Hb M Hyde Park variant, in which the histidine residue at position 92 of the β-globin chain has been substituted by a tyrosine residue, which is at the opposite (proximal) side of the porphyrin ring compared to the Hb M Saskatoon, methemoglobin also could not be detected [23]. This observation indicates that unstable Hb M variants interfere with absorption spectra of stable variants in blood gas co-oxymetry, disabling the measurements of the of stable hemoglobins, like oxyHb (OHb), deoxyHb (HHb), carboxy Hb (COHb) and stable methemoglobin (metHb) [24].

Table 1. Clinical chemistry and hematological parameters of the patient.

Laboratory test	Outcome	Reference interval
Hb (g/dL)	12.3	12.1–16.1
Ht (L/L)	0.37	0.35–0.45
MCV (fL)	105	80–100
Erythrocytes (10^{12}/L)	3.6	4.0–5.0
Reticulocytes (10^{9}/L)	160	30–110
$HbA1_c$ (mmol/mol)	12.3	20.0–42.0
LD (U/L)	155	<245
Total bilirubin (µmol/L)	12	<21
Folic acid (nmol/L)	10	9–61
Vitamin B12 (pmol/L)	226	145–569
Plasma iron (µmol/L)	14	9–30
Transferrin (µmol/L)	28.7	25.0–45.0
Transferrin saturation (%)	24	0–45
Ferritin (µg/L)	27	10–250
eGFR (CKD-EPI) (mL/min/1.73m^2)	84	60–200

Notes: Hb, hemoglobin; Ht, hematocrit; MCV, mean corpuscular volume; LD, lactate dehydrogenase.

Methemoglobinemia

Methemoglobinemia may arise as a result of genetic or acquired causes. Acquired methemoglobinemia is most prevalent and commonly caused by oxidative stress, which can have exogenous or endogenous origins. Endogenous forms of oxidative stress include but are not limited to free radicals such as

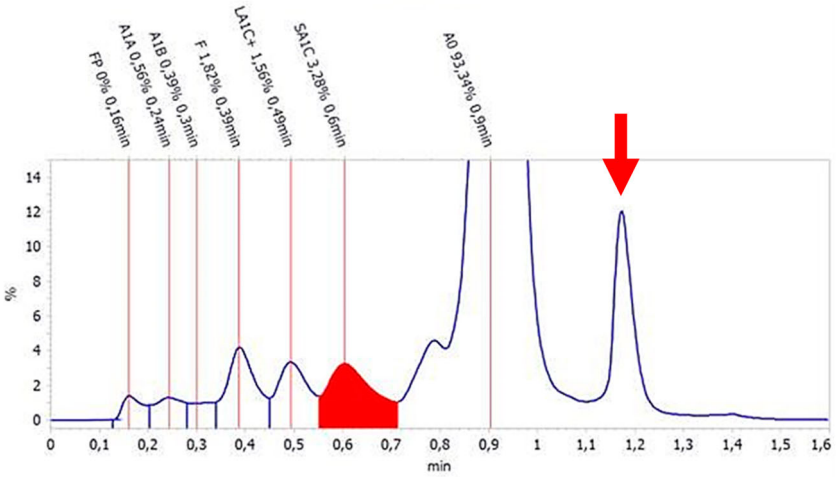

Figure 2. Chromatogram of the patient's sample analyzed with a Tosoh HLC-723 G8 analyser using the standard HbA1c mode. HbA1c, in red, measured at 3.3% in this mode (12.3 mmol/mol) at 0.6 min. An additional unidentifiable peak is shown at approximately 1.15 min (arrow), indicating the presence of abnormal unstable Hb M Saskatoon.

nitric oxide, hydrogen peroxide and hydroxyl radicals. Exogenous substances may also trigger the oxidation of hemoglobin and this occurs most often as a result of medication. Dapsone, topical anesthetics (benzocaine, lidocaine), anti-malarial agents (chloroquine, hydroxychloroquine) and street drugs account for the majority of iatrogenic methemoglobinemia [25,26]. In addition to the formation of methemoglobin in healthy patients, these drugs may seriously exacerbate the condition of patients who are prone to methemoglobinemia due to genetic mutations causing hemoglobinopathies. Genetic defects that result in methemoglobinemia are commonly found in the *CYB5R3* gene, which encodes the cytochrome b5 reductase enzyme. This enzyme is responsible for the reduction of the Fe^{3+} ion in methemoglobin to Fe^{2+}. Mutations in this gene can both affect the enzymatic stability as well as its catalytic activity [27,28]. Most other genetic defects giving rise to (unstable) methemoglobinemia are hemoglobinopathies that result in the formation of HbM variants due to the defects in the alpha, beta, or gamma globins [29].

Notes: The alternative name for the Hb variant is presented in the second column.

Precautions and treatment options

Methemoglobinemia can potentially be life-threatening, but only patients with methemoglobin levels >30% or >20% accompanied with symptoms require treatment. Treatment at lower levels should be considered in patients presenting with concomitant anemia or with a known cardiorespiratory medical history [30]. The therapy depends largely on the cause of methemoglobinemia. In acquired methemoglobinemia, besides cessation of the causative agent and supportive therapy, methylene blue (MB) is preferred as treatment and previous reports have shown a rapid effect when administered in subsequent doses of 1–2 mg/kg intravenously up to a maximum of 7 mg/kg over 24 hours. However, MB should be administered with caution, since its effect is dependent on glucose-6-phophate dehydrogenase (G6PD) and NADH-MetHb-reductase. G6PD delivers nicotinamide adenine dinucleotide phosphate (NADPH) needed to convert MB to the metabolic product leukomethylene blue, which acts as a reducing agent to convert methemoglobin to hemoglobin. Therefore,

MB is contraindicated in patients with G6PD deficiency or proven NADH-MetHb-reductase deficiency.

Alternatively, ascorbic acid acts as an antioxidant and has also shown to be effective in decreasing the level of methemoglobin. Ascorbic acid appears to act slower than MB taking up to 1–3 days as it often requires repetitive dosing of 2–40 g administered intravenously [31]. Therefore, MB is usually preferred over ascorbic acid in acute methemoglobinemia although no randomized controlled trials have been performed to compare both treatments.

In the case of severe refractory methemoglobinemia, treatment with exchange transfusions and hyperbaric oxygen has shown improvement. However, little evidence exists concerning these two modalities which therefore remain a last resort in severe and refractory methemoglobinemia [32,33].

In Hb M disease, treatment with both MB and ascorbic acid is ineffective because the ferric state in Hb M is stabilized. The Hb M structural variants are unstable or characterized by decreased oxygen affinities rather than other causes of methemoglobinemia, such as oxidative stress or enzymatic deficiency (CYB5R3). Treatment with MB would be undesirable, because as an oxidating agent, MB itself poses a risk of hemolytic anemia and could exacerbate methemoglobinemia. Exposure to any oxidizing agent should be avoided since these patients exhibit an increased risk of progression to symptomatic methemoglobinemia. Since there are no effective treatment options for patients with Hb M disease, counseling should focus on reassuring the patient about their benign condition and offering genetic testing to first-degree relatives.

The patient in our case was prescribed oral folic acid 0.5 mg and vitamin B-12 1000 µg daily. Two months later, our patient reported increased fitness. Vitamin B12 and folic acid levels were measured 6 months after the start of oral supplements and measured at 83 nmol/L folic acid and 500 pmol/L vitamin B12. We hypothesize that an increased erythrocyte turnover in this patient with Hb M disease in combination with a relatively low level of serum folate and vitamin B-12 may have triggered a symptomatic anemia with a relative increase of dysfunctional Hb M.
