ABSTRACT

Background. Anti-CD20 B-cell depletion has not shown superior efficacy to standard immunosuppression in patients with systemic lupus erythematosus (SLE). Besides trial design, potential explanations are incomplete B-cell depletion in relation to substantial surges in B-cell-activating factor (BAFF). To improve B-cell targeting strategies, we conducted the first study in SLE patients aimed at investigating immunological effects and feasibility of combining rituximab (RTX; anti-CD20) and belimumab (BLM; anti-BAFF).

Methods. Reported is the long-term follow-up of a Phase 2 proof-of-concept study in 15 patients with SLE including 12 (80%) with lupus nephritis (LN).

Results. In 10/15 (67%) patients, a clinical response was observed by achievement of lupus low disease activity state, of which 8 (53%) continued treatment (BLM + ≤ 7.5 mg prednisolone) for the complete 2 years of follow-up. Five patients (33%) were referred to as ‘non-responders’ due to persistent LN, major flare or repetitive minor flares. Out of 12 LN patients, 9 (75%) showed a renal response including 8 (67%) complete renal responders. All anti-dsDNA⁺ patients converted to negative, and both anti-C1q and extractable nuclear antigen autoantibodies showed significant reductions. CD19⁺ B cells showed a median decrease from baseline of 97% at 24 weeks, with a persistent reduction of 84% up to 104 weeks. When comparing responders with non-responders, CD20⁺ B cells were depleted significantly less in non-responders and double-negative (DN) B cells repopulated significantly earlier.

Conclusions. Combined B-cell targeted therapy with RTX and BLM prevented full B-cell repopulation including DN

B cells, with concomitant specific reduction of SLE-relevant autoantibodies. The observed immunological and clinical benefits in a therapy-refractory SLE population prompt further studies on RTX + BLM.

Keywords: autoantibodies, autoimmune glomerulonephritis, immune complex-mediated membranoproliferative, lupus nephritis, rituximab/belimumab, systemic lupus erythematosus

INTRODUCTION

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease in which loss of tolerance to nucleic acids and their binding proteins results in generation of autoantibodies (e.g. anti-DNA, anti-chromatin or anti-histone autoantibodies), leading to inflammation potentially involving almost every organ system, including the kidney [1]. Lupus nephritis (LN) is seen in 29–82% of patients [2] and remains difficult to treat, with short-term complete renal response (CRR) rates around 10–40% at 12 months [3] and occurrence of end-stage renal disease in 10% of LN patients [4]. Together with the fact that patients with refractory SLE receive high cumulative dosage of toxic immunosuppressive medication, exploration of new therapeutic options is important.

Since autoantibodies contribute to renal pathology in SLE, targeting autoreactive B cells has continued interest as a possible strategy for treating SLE patients. Targeting B cells with the anti-CD20 monoclonal antibody (mAb) rituximab (RTX) has been unsuccessful in randomized trials in both patients with extra-renal [5] and those with renal SLE [6]. Belimumab (BLM), an anti-B-cell-activating factor (BAFF) mAb, was

KEY LEARNING POINTS

What is already known about this subject?

- Anti-CD20 B-cell depletion has not been superior to standard immunosuppressive regimens where incomplete B-cell depletion is associated with non-response as well as increased levels of B-cell-activating factor (BAFF) after B-cell depletion.
- BAFF can be neutralized by the novel monoclonal antibody belimumab (BLM), which demonstrated superior efficacy in preclinical animal studies.
- The combination therapy of anti-CD20 B-cell depletion by rituximab (RTX) with the addition of BAFF neutralization by BLM has only been published in a few case reports.

What this study adds?

- The study is the first, proof-of-concept study designed to investigate the long-term feasibility of combining RTX + BLM in systemic lupus erythematosus (SLE) patients, which was well-tolerated without major safety issues throughout the 2-year follow-up and allowed the discontinuation of mycophenolate mofetil (MMF) associated with significant immune reconstitution.
- RTX + BLM led to long-lasting and specific reduction of several anti-nuclear autoantibodies and prevented the full repopulation of B cells.
- Response to treatment was associated with more profound depletion of CD20⁺ B cells and prolonged suppression of double-negative B cells.

What impact this may have on practice or policy?

- RTX + BLM achieved targeting of pathological autoimmunity in SLE and showed a potential clinical benefit. Because no major safety issues were raised throughout the study, RTX + BLM can safely be studied in further clinical trials to establish its efficacy compared with standard treatment.

approved for the treatment of active SLE. Approval of BLM included a special warning on its use with concomitant B-cell targeted therapy; however, RTX + BLM provides an opportunity to target the surge in circulating BAFF levels after B-cell depletion, thereby minimizing the survival of autoreactive B cells [7, 8].

The concept of combining anti-CD20 B-cell depletion with anti-BAFF cytokine inhibition is supported by mice studies showing the importance of the micro-environment and cellular competition in anti-CD20 mAb-mediated killing of B cells where cellular competition for survival factors (e.g. availability of BAFF) can underpin resistance to anti-CD20 therapy [9]. The importance of BAFF levels in anti-CD20 therapy is

further illustrated in a study using an *in vitro* model of mature B cells, where BAFF was able to inhibit CD20-mediated apoptosis [10]. Additionally, in different lupus mouse models, a combination of anti-CD20 and anti-BAFF therapy led to improved disease control compared with each treatment separately or cyclophosphamide [11]. We have previously reported on the effects of combination treatment with CD20 and BAFF targeting in SLE patients [12]; however, the long-term effects on B-cell repopulation and B-cell composition have not been reported yet.

'Synergetic B-cell immunomodulation in SLE' (Synbiose) was designed as the first translational, single-arm, proof-of-concept study in SLE patients aimed at investigating the underpinning, immunological hypothesis of combining RTX + BLM in severe, refractory SLE patients. We previously reported the early effects of RTX + BLM, demonstrating a reduction in anti-nuclear antibodies (ANAs) and regression of excessive neutrophil extracellular trap formation [12]. We now report long-term effects of RTX + BLM on depletion of ANAs, B-cell repopulation and clinical response during 2 years of follow-up.

MATERIALS AND METHODS

Study design

The Synbiose study is a Phase 2, single-arm, open-label proof-of-concept study in which 'severe, refractory SLE' patients were included, defined as persisting or progressive disease despite conventional immunosuppressive treatment with an SLE disease activity index (SELENA-SLEDAI) score at time of inclusion of ≥ 12 points. Patients were treated with intravenous methylprednisolone pulse therapy at baseline, 1000 mg intravenous RTX at Weeks 0 + 2 and with intravenous 10 mg/kg BLM at Weeks 4 + 6 + 8 and then every 4 weeks until 104 weeks. Mycophenolate mofetil (MMF) was started but quickly tapered to avoid cumulative over-immunosuppression. Oral prednisolone was started at 1 mg/kg/day (maximum 60 mg/day) and tapered towards maintenance dose of ≤ 7.5 mg/day. The study was approved by the Dutch Leiden University Medical Center medical ethics committee and all patients provided written informed consent. The study was registered at ClinicalTrials.gov (NCT02284984).

A fully detailed methods section with description of the clinical parameters, methods and materials used for experiments and statistical analysis is available as [Supplementary data](#), File S1.

RESULTS

Summarized patient characteristics

Baseline characteristics from all included patients have been reported previously [12]. Briefly, 16 patients (88% female) were included, with median age of 31 years (range 19–51). All patients had refractory disease, of which 12 (80%) had active LN at baseline. One patient experienced severe hypogammaglobulinaemia at Week 8 after completion of methylprednisolone and RTX; therefore, BLM treatment was not initiated. This patient was excluded from the long-term follow-up study. Fifteen

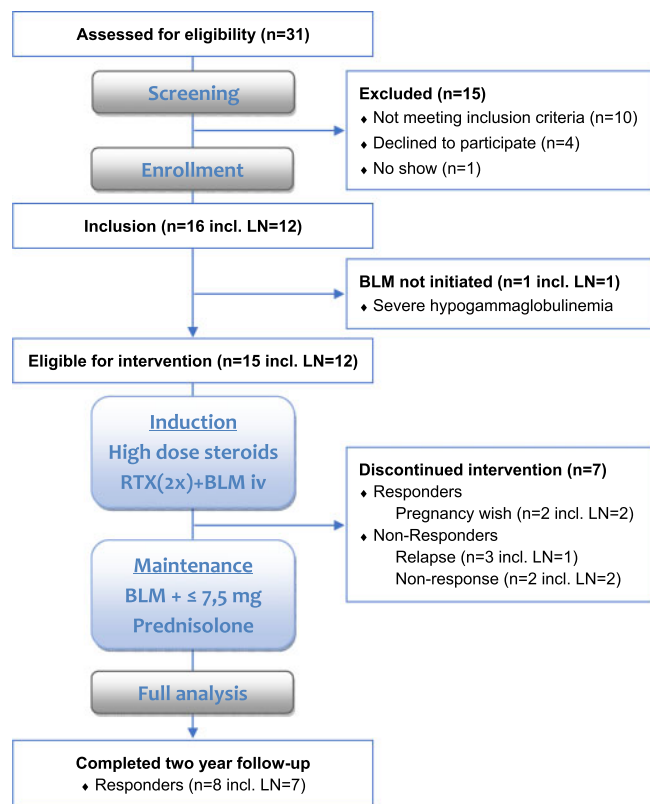

FIGURE 1: Flow diagram of patients.

patients reached the primary endpoint at Week 24. A flow diagram of the patients is included in Figure 1.

Clinical response

During the study period, 10 of 15 (67%) patients had a clinical response. At Week 104, this response was 8 of 13 (62%). Eight patients (53%) finished the complete follow-up of 104 weeks. Two patients with a clinical response stopped BLM treatment at Week 24, based on a pregnancy wish (Patients #14 and #15 in Figure 2). Clinical response is illustrated in Figure 2A defined by the time for patients to achieve and remain in lupus low disease activity state (LLDAS) and by attaining a renal response in patients with active LN at baseline (Figure 2B). In the eight responders available for analysis over the 2-year follow-up, the median time to the first achievement of LLDAS was 24 weeks (range 12–36) and the median time on LLDAS was 76 weeks (56–92). One patient had a minor flare with pericarditis and received 0.5 mg/kg prednisone and colchicine (Patient #3) followed by quick resolution of disease activity. At Week 104, seven of eight patients received maintenance therapy with glucocorticoids with median (range) dose of 7.5 mg/day (2.5–7.5), all patients continuously used hydroxychloroquine and BLM (Figure 2C).

In patients with active LN at baseline, 9 of 12 (75%) had a renal response during the trial period with CRR at Week 104 in 6 of 10 (60%), all had proteinuria <0.5 g/day. In renal responders that finished the study period ($n = 7$), proteinuria decreased from a median (range) of 4.6 g/day (1.3–11.2) to 0.3 (0.1–1) ($P = 0.02$ at Week 104), representing a median decrease of 96%. Despite rapid decline upon treatment, Patient #4 did not reach

CRR due to persistent proteinuria >0.7 g/day, which clinically correlated with histologically proven chronic renal damage warranting the continuation in the study.

Five patients were classified as ‘non-responders’ and dropped out due to clinical relapse or non-response necessitating alternative induction treatment: two patients had a major flare: Patient #10 experienced a renal flare at Week 46 requiring cyclophosphamide treatment and Patient #11 experienced recurrence of transverse myelitis at Week 44, upon which induction treatment with RTX + steroids was given. Patients #12 and #13 had persistent features of active LN and were excluded at Week 24, as described in more detail previously [12]; one was treated with cyclophosphamide, while other was given an experimental induction treatment within another study. Patient #9 was excluded at Week 74 due to a recurrent minor flare (complement consumption, anti-dsDNA positivity and arthritis) and was switched to leflunomide with high-dose steroids (0.5 mg/kg/day). Baseline characteristics of the responders and non-responders are depicted in Table 1.

Long-term safety

Treatment-emergent adverse events (TEAEs) during the study period are summarized in Table 2. In all patients, adverse events (AEs) were reported with five serious AEs (SAEs) in four patients (27%) due to hospitalization for the suspicion of infection ($n = 3$) or laparoscopic cholecystectomy ($n = 1$) because of cholelithiasis. In all cases, suspected infections were gastrointestinal without detectable pathogen, requiring a one-night hospital admission without the need for antibiotic treatment. In nine patients (60%), a minor infection was observed, of which upper respiratory tract infections were most prevalent. A detailed description of all infectious AEs is provided in Supplementary data, File S2. Two patients suffered from mood disorders; one patient had glucocorticoid-induced mood disorder and psychosis after methylprednisolone infusions and another patient experienced depressive symptoms started at Week 95, leading to study treatment interruption to exclude progressive multifocal leukoencephalopathy (PML). Once PML and neuropsychiatric SLE were ruled out, a mild depressive disorder was diagnosed and BLM treatment reinstated.

Long-term effects of RTX + BLM on B-cell immunology

By employing high-sensitivity flow cytometry, we observed prolonged inhibition of B-cell repopulation: CD19⁺ B cells declined from a median of 100×10^6 cells/L (20.5; 248×10^6) at baseline to 3.75×10^6 cells/L (0.53; 64.7×10^6) ($P = 0.005$) at Week 24, representing a median decrease of 97% from baseline. At Week 104, the median number of CD19⁺ B cells was 13.6×10^6 cells/L (10.7; 47.3×10^6), representing a median decrease of 84% (–92; +22) from baseline (Figure 3A and B), illustrating that B cells did not repopulate to baseline values during continued BLM treatment. The low-level repopulation of B cells was dominated by an early recurrence of plasmablasts at Week 24 up to a median decrease of 17% [0.66×10^6 cells/L (< 10^4 ; 18.3×10^6)] and to a lesser extent repopulation of switched memory B cells up to a median decrease of 71% [2.03×10^6 cells/L (< 10^4 ; 41.9×10^6)] compared with baseline

FIGURE 2: Overview of the clinical responses, renal responses and concomitant immunosuppression upon RTX + BLM treatment. (A) Achievement of LLDAS over time. (B) Achievement of a renal response in patients included with active LN ($n = 12$). CRR was achieved when proteinuria ≤ 0.7 g/day, normal serum albumin, stable kidney function and normal urinary sediment; partial response: >0.7 – 2.9 g/24h with a decrease in proteinuria of $\geq 50\%$ from baseline, serum albumin >30 g/L and stable kidney function. When patients did not meet any of these criteria, they were considered to have persistent active LN. (C) Overview of concomitant treatment with BLM, MMF and prednisolone throughout the study's follow-up. Patient numbers mentioned on the y-axis correspond between the three figures. SACQ, serologically active (positive antibody and or low complement) clinically quiescent.

values. Only from 48 weeks onwards did the resurgence of immature B cells occur, with return of transitional B cells [$+52\%$, 0.78×10^6 cells/L (0.19; 2.23×10^6)] and non-switched memory

B cells [-19% , 1.53×10^6 cells/L (1.02; 3.19×10^6)] at Week 104. Interestingly, continuous BLM treatment prevented complete repopulation of naïve B cells [-81% , 6.07×10^6 cells/L

^fNormal C4: 95–415 mg/L.

(0.70; 25.8×10^6) as well as double-negative (DN) B cells [-82% , 2.48×10^6 cells/L (0.46; 4.25×10^6)] at 104 weeks (Figure 3C and D).

Long-term immune reconstituting effects

In the RTX + BLM treatment strategy, patients were able to taper steroids and stop MMF treatment before or at 24 weeks (Figure 2C). As a consequence, the observed low levels of T and NK cells at baseline significantly increased over time. Circulating CD4⁺ T cells increased from 234×10^6 cells/L (116; 530×10^6) at baseline to 658×10^6 cells/L (285; 1270×10^6) (P = 0.02 at Week 104), CD8⁺ T cells, from 276×10^6 cells/L (12.1; 418×10^6) at baseline to 493×10^6 cells/L (237; 1700×10^6) (P = 0.04) and in NK cells from 18×10^6 cells/L (0.4; 133×10^6) to 97×10^6 (38; 221×10^6) (P = 0.08; Figure 3E).

Long-term effects of RTX + BLM on humoral autoimmunity

With respect to the effects of RTX + BLM on immunoglobulin levels, total immunoglobulin G (IgG) levels in comparison with baseline levels [median 11.3 g/L (5; 23.6)] initially decreased at 12 weeks [7.8 g/L (2.6; 14.4), P = 0.05] and stabilized from 24 weeks onwards [9.7 g/L (3.4; 16.4), Supplementary data,

File S3]. At Week 104, IgG levels increased with 6.4% (−44; +30) compared with baseline levels (Figure 4A). IgA levels remained stable over the follow-up period while IgM levels gradually declined from 0.72 g/L (0.26; 1.06) at baseline to 0.27 g/L (0.2; 0.63) (P = 0.008) at Week 72 and increased to 0.37 g/L (0.2; 0.73) (P = 0.02) at Week 104 (Supplementary File S3). With regard to (auto)antigen-specific IgG, anti-tetanus and anti-rubella IgG remained stable during follow-up (Figure 4B and C), while anti-varicella zoster virus IgG (anti-VZV IgG) showed a significant decrease (Figure 4D) from 3435 mIU/mL (442; 4000) at baseline to 2436 (404; 3625) (P = 0.02) at Week 104. Of note, all measured anti-VZV IgG levels were within protective ranges.

Anti-dsDNA levels of 268 AU/mL (50; 827) at baseline decreased at Week 24 to 29.6 (0; 104.5) (P = 0.02) equal to a median decrease of 87% (−100; +3) (Figure 4E). By Week 48 up to Week 104, all anti-dsDNA-positive patients converted to negative on immunofluorescence (CLIFT) with a median titre of 52 (23; 132) (P = 0.04) at Week 104, equal to a median decrease of 81% (−91; +95) from baseline. Similar reductions in anti-RNP70, anti-U1RNP, anti-Sm and anti-C1q autoantibodies levels were observed as illustrated in Figure 4F–I. Briefly, at 104 weeks, anti-RNP70 antibody levels were reduced with a median of 88% (−94; −48) (P = 0.25), anti-U1RNP with 41% (−79; −31) (P = 0.13), anti-Sm with 30% (−97; −13) and anti-C1q antibodies with 60% (−86; +2) (P = 0.03). The relative

reductions of autoantibody compared with alloantibody levels over total IgG is illustrated in Figure 4J, demonstrating that RTX + BLM preferentially targeted humoral autoimmunity.

With respect to complement levels, normalization of C3 levels was seen at 104 weeks in seven of eight patients with median C3 levels of 1.0 g/L (0.8; 1.3) compared with baseline C3 levels of 0.6 g/L (0.3; 0.8) (P = 0.008). Also, C4 levels increased from 54 (35; 80) to 147 mg/L (74; 279) (P = 0.25; Supplementary data, File S3).

Associations of immunological effects with clinical response to RTX + BLM

We investigated immunological parameters that could potentially discriminate long-term responders (n = 8) from non-responders (n = 5) depicted in Supplementary data, Files S3 and S4. We observed that, not unexpectedly, after 4, 12 and 24 weeks, a significantly larger increase in C3 levels was seen in responders versus non-responders (respectively, 27% versus 0%, P = 0.03, 42% versus 8%, P = 0.01 and 79% versus 8%, P = 0.008). With high sensitivity flow cytometry, we observed two noteworthy findings: first, the total number of CD20⁺ B cells at Week 24 was significantly lower in responders [1.83×10^6 (0.10; 17.2×10^6)] compared with the non-responders [15.8×10^6 (3.01; 22.1×10^6), P = 0.045]. Secondly, repopulation of DN B cells occurred earlier in the non-responder group, at Week 24 (12; 24) [nadir levels of 0.48×10^6 cells/L (0.17; 1.02×10^6)], while in responders repopulation of DN B cells occurred at Week 72 (48; 104) (P = 0.0008) [nadir levels of 0.32×10^6 (0.11; 2.34×10^6)]. Finally, a trend for higher baseline BAFF levels was found in non-responders versus responders [respectively, 0.97 ng/mL (0.48–1.4) versus 0.44 ng/mL (0.26; 0.91), P = 0.06], while the decrease at 24 weeks was similar between responders [0.11 ng/mL (0.09–0.19)] and non-responders [0.15 ng/mL (0.08–0.35), P = 0.12].

DISCUSSION

In this proof-of-concept study, the long-term immunological and clinical effects of RTX + BLM in patients with severe, refractory SLE (including LN) are described. Long-lasting, specific reduction of anti-dsDNA, anti-C1q and even extractable nuclear antigen autoantibodies were observed and full B-cell repopulation was prevented throughout the 2-year follow-up. Clinical response persisted in two-thirds of the patients during follow-up with maintenance treatment consisting of BLM and low-dose prednisolone and allowed discontinuation of MMF associated with significant immune reconstitution. Profound depletion of CD20⁺ B cells, prolonged suppression of DN B cells and higher serum BAFF levels potentially discriminated responders from non-responders, and should be validated in larger clinical trials.

The study encompassed refractory SLE patients in which we were unable to continue immunomonitoring in non-responders who required different conventional induction therapies or in responders with a pregnancy wish. Within this limitation, we investigated potential predictors of non-response to RTX + BLM predominantly in the first 6 months. It is known

FIGURE 3: Longitudinal kinetics of circulating immune cells >2 years of follow-up after RTX + BLM treatment ($n = 8$ responders). (A and B) RTX + BLM prevents the complete repopulation of circulating B cells. Depicted are individual values of all responders with the median in bold representing change of $CD19^+$ B cells in (A) absolute numbers and (B) the percentage of change from baseline. (C and D) Repopulation of B-cell subsets upon RTX + BLM. Depicted are the median change from baseline in (C) absolute numbers and (D) the percentage of change of the following B-cell subsets: plasmablasts ($CD3^- CD38^{bright} CD27^{bright} CD19^+$), non-switched memory B cells ($CD3^- CD19^+ CD27^+ IgD^+$), switched memory B cells ($CD3^- CD19^+ CD27^+ IgD^-$), naïve B cells ($CD3^- CD19^+ CD27^- IgD^+$), DN B cells ($CD3^- CD19^+ CD27^- IgD^-$) and transitional B cells ($CD3^- CD19^+ CD38^{bright} CD24^{bright}$). (E) Significant reconstitution of circulating $CD4^+$ T cells ($CD3^+ CD4^+$), $CD8^+$ T cells ($CD3^+ CD8^+$) and NK cells ($CD16^+ CD56^+$). Depicted are the median changes from baseline in absolute numbers.

that the B-cell-depleting potential of RTX has an inter-person variation and that the association of clinical outcome with the depth of B-cell depletion has been made [13, 14]. We found that less profound depletion of $CD20^+$ B cells was associated with a poor response, in line with findings of a *post hoc* analysis of the LUNAR trial [15] where rapidness and duration of complete peripheral B-cell depletion were associated with complete response. Our observations in B-cell subsets are also in line with a recent study investigating B-cell subsets with Cytof in SLE patients during BLM therapy [16], where long-term depletion of $CD20^+$ B cells and naïve B cells was seen. The loss of naïve B cells during BLM therapy has been shown before [16–18]. We found that only transitional B cells and plasma cells repopulated to baseline levels and that naïve B-cell repopulation present at 48 weeks remained suppressed for the duration of the follow-up period. Even more interesting are the DN B cells that showed a less profound depletion but did not repopulate throughout the 104 weeks. Additionally, we observed that early repopulation of DN B-cell associated with poor response. DN B cells in SLE are shown to be a major source of autoantibody-secreting cells (ASCs) [19], and the number of DN B cells is associated with

disease activity and the presence of LN [20]. Moreover, further characterization of the DN B-cell population elucidated that these cells were hardly found in healthy or disease controls and were highly responsive to Toll-like receptor-7 stimulation inducing their differentiation to ASCs [20]. Unfortunately, we were limited in the depth of phenotyping DN B cells in this study, partly because this subpopulation had not been described at the time of study design and initiation. Notwithstanding, taken together with our observation that memory B cells and plasmablasts fully repopulated after RTX + BLM while long-lasting reductions of autoantibodies persisted, this suggested that a prolonged suppression of autoreactive DN B cells can be beneficial to SLE patients. Therefore, DN B cells are highly interesting biomarker to further study in the context of RTX + BLM treatment for SLE and LN patients.

Throughout the 2-year follow-up, no major safety issues were raised. The frequency of TEAEs was registered in 100% of patients containing 27% SAEs and 60% infections and was comparable to the LUNAR (99, 27 and 85%, respectively) and BLISS studies (93, 42 and 75%, respectively). Also, preliminary results of the CALIBRATE study (NCT02260934), in which

FIGURE 4: RTX + BLM resulted in prolonged, specific reduction of autoantibody levels >2 years follow-up ($n = 8$ responders). (A–D) Percentage change of physiological antibody levels are depicted, i.e. total IgG, anti-tetanus toxoid (TT), anti-rubella and anti-VZV antibodies. (E–G) Percentage change of SLE-relevant autoantibodies are depicted, i.e. anti-dsDNA ($n = 8$), anti-U1RNP ($n = 4$), anti-RNP70 ($n = 3$), anti-Sm antibodies ($n = 3$) and anti-C1q antibodies ($n = 7$). (J) To illustrate specific reductions in physiological antibody (anti-TT, anti-rubella and anti-VZV) and autoantibody levels (anti-dsDNA, anti-RNP70, anti-U1RNP, anti-Sm and anti-C1q), normalized ratio over total IgG was calculated and compared with baseline.

43 LN patients were randomized to receive RTX, cyclophosphamide and prednisone with or without additional BLM treatment, showed a non-significant difference on Grade 3 or higher infectious AEs (9% with BLM versus 23% without BLM, $P = 0.25$), confirming that RTX + BLM is well-tolerated. In addition, the CALIBRATE study reported 52% renal responders in the BLM group versus 41% in the placebo group. This non-significant difference could possibly be explained by the use of cyclophosphamide for induction treatment, in contrast to mycophenolate in the present study and the relative high dose of prednisolone maintenance (10 mg/day) continued throughout 2 years. It is of interest that preliminary reports from the CALIBRATE study showed impaired B-cell repopulation during BLM treatment as well as specific decrease in the naïve B-cell compartment upon BLM.

Our study observed 60% CRR rate at 104 weeks using the pre-defined CRR criteria containing proteinuria levels of ≤ 0.7 g/24 h, in comparison with ≤ 0.5 g/24 h used by landmark LN trials (LUNAR [6], ACCESS [21], ALLURE [22] and ALMS [23]). Reanalysis of the results showed that patients with a CRR at 104 weeks all have proteinuria levels < 0.5 g/24 h. Based on LLDAS, clinical response to RTX + BLM was observed in 62% of patients in the present study. We demonstrated that responders to RTX + BLM had lasting LLDAS, which is associated with reduced damage accrual [24] and better quality of life [25], and can be used as an endpoint for clinical trials [26]. In this small trial, clinical benefit was achieved with RTX + BLM and persisted despite tapering of steroids to a dosage ≤ 7.5 mg and discontinuation of MMF. Although unconventional, tapering of MMF was added in the study design because at that time

combined B-cell targeting with RTX + BLM had not been given to patients structurally (besides case reports [27–31]) and was intended to avoid over-immunosuppression which was fundamental of the previously mentioned label warning of BLM. Indeed, MMF tapering allowed for significant reconstitution of circulating CD4⁺ T cells and is a unique achievement for LN patients. Altogether, these data are reassuring for further studies to study clinical efficacy of RTX + BLM for active SLE including LN in a randomized setting.

It is noteworthy to establish that the primary null-hypothesis to study the combination of RTX + BLM, i.e. to induce long-term B-cell depletion and indirectly (autoreactive) plasmablast depletion, was wrong. The null-hypothesis was based on dual B-cell therapy in murine studies [11] but the contrary was observed: plasmablasts repopulated fastest among the studied B-cell subsets. Importantly, this was not associated with (recurrence of) disease activity or with autoantibodies. It was remarkable that RTX + BLM preferentially targeted humoral autoimmunity without affecting protective ranges of anti-viral antibody levels. It can be speculated that autoreactive B cells have an increased BAFF dependence due to the continuous presence of antigens compared with alloreactive B cells. This might also explain the significant drop, although not below protective levels, of antibodies against the VZV, which remains inactive in the body for many years.

The most important limitations of this study are the small number of treated patients and the single-arm design. The latter impairs the ability to place the observed effects into perspective to standard treatment regimens and it could be argued that the observed effects are solely due to RTX treatment combined with concomitant immunosuppressants. However, profound B-cell depletion by RTX has shown to be highly variable in SLE patients with a median time to repopulation around 32 weeks [32], and only 0–11% of patients with sustained low B-cell counts for 1–2 years without retreatment [13, 32–34]. In a comparable cohort of seven severe, refractory SLE patients retreated with RTX, a median duration of clinical response of 13 months and B-cell depletion of 6 months were reported [35], together suggesting a synergistic role of BLM in RTX-treated SLE patients.

In conclusion, this study was the first to pioneer the combination of RTX + BLM in patients with severe, refractory SLE aiming to establish its feasibility and better understand its immunological effects.

RTX + BLM treatment appears to be a promising strategy to target pathological autoimmunity mechanisms in SLE with suggestions towards beneficial clinical effects. We are therefore reassured that RTX + BLM can be safely studied in further clinical trials to assess its added value in the treatment of SLE patients with and without renal involvement.

SUPPLEMENTARY DATA
