Abstract

Objective The main aim was to explore the changes in hand-grip strength in patients with Duchenne muscular dystrophy (DMD) aged 5–29 years. Secondary aims were to test the effect of mutation, ambulatory status and glucocorticoid use on grip strength and its changes over time and to compute the number of subjects needed for a clinical trial to stabilize grip strength. **Methods** The analysis was performed on data collected during five international natural history studies on a cohort of DMD patients. Two hundred and two patients with genetically proven DMD were pooled from five different natural history studies. Excepting 13 patients with only one visit, the mean duration of follow-up was 2.2 ± 1.6 years. A total of 977 measurement points were collected. Grip strength was measured on the dominant side with a high precision dynamometer. The analysis was performed using absolute values and normalized values expressed in percentage of predicted values for age.

Results For absolute values, grip strength typically increased in ambulatory boys and decreased in non-ambulatory patients. However, when normalized, grip strength was already reduced at age 5 years and thereafter continued to fall away from normal values. The weaker the patients, the less strength they are prone to lose over again.

Interpretation Grip strength constitutes a sensitive and continuous outcome measure that can be used across all stages of DMD. Its measurement is easy to standardized, can be used in ambulatory and non-ambulatory patients and does not present any floor or ceiling effect. It is thus attractive as an outcome measure in therapeutic trials.

Keywords Duchenne muscular dystrophy · Grip strength · Outcome measures

Introduction

Duchenne muscular dystrophy (DMD) is a degenerative genetic muscle disease in which mutations in the dystrophin gene lead to muscle fiber degeneration and gradual replacement of muscle by fat and connective tissue. The clinical

onset of symptoms usually appears in the lower limbs of boys before 4 years of age. DMD weakness typically affects proximal muscles first, with loss of distal muscle strength and function later. Muscles of the hands are thus affected later in the disease course, however also become progressively weakened and eventually paralyzed in the second and

third decades of life. Despite the importance in maintaining strength and independent function as long as possible for young men with DMD [25], only few recent studies have focused on the upper limbs of DMD patients [6, 14, 17–19]. Hand and arm function is indeed associated with many domains of daily life activities (physical performance such as holding a glass, writing, turning a door knob, but also psychological and social functioning), so a key element in improving these may be to preserve arm function [9, 12].

Grip strength can be impaired from a young age in DMD, even long before the loss of ambulation [19, 25]. It is correlated with the degree of physical disability [13, 21], is sensitive to change in the non-ambulatory DMD population [21] and presents excellent reliability [22]. Maximal grip strength (MGS) measured with an appropriate handgrip dynamometer is a continuous variable that does not present any floor or ceiling effects in DMD [22]. However, these results have been observed on a rather limited number of patients and on a limited age range. Furthermore, reporting MGS as an absolute value rather than as a percentage of predicted values induces a confounding interference with physiological growth [6]. Indeed stature has been shown to be the main predictor of muscle strength during normal childhood development [5], with a smaller stature yielding lower strength. As height influences stride length, hence the distance walked within 6 min. We hypothesized that expressing MGS in percentage of predicted values rather than in absolute values could increase sensitivity to change by reducing the confounding factors of growth and maturation.

The main aim of this study was to explore the progression of maximal grip strength during the course of DMD over a large range of age. Secondary aims were to test the effect of ambulatory status, glucocorticoid use and mutation on MGS and to compute the number of subjects needed for a clinical trial aiming to stabilize grip strength.

Methods

Study design

The results of MGS were gathered from five Ethical Review Board-approved natural history studies in DMD conducted between 2010 and 2019 (Table 1) in Paris (Institute of Myology), London (NIHR Great Ormond Street Biomedical Research Center), Newcastle (John Walton Muscular Dystrophy Research Center), Nijmegen (Radboud University Medical Center) and Leiden (Leiden University Medical Center). Molecular diagnosis of DMD was the only common inclusion criteria to all protocols. All patients or legal guardians for patients younger than 18 years gave written informed consent prior to participation in the studies.

Measurement procedure

MGS was measured using the MyoGrip device [22] (Fig. 1) every 6 or 12 months depending on the study protocol. The Myogrip dynamometer is an electronic device specifically developed for measuring isometric grip strength in very weak patients, but which can also be used in healthy subjects. It measures forces in kilograms (kg) from 0 to 90 kg with a resolution of 0.01 kg and an accuracy of 50 g over the whole range of measurement. Handle size is adjustable in a continuous way to fit at best the hand size of the subjects.

The physiotherapists of all centers were trained to use the same standardized operating procedure. All tests were performed with patients seated on a chair or in their wheelchair facing a table with the forearm placed on the table or on the wheelchair shelf. Before each test, patients were given a description of the grip task, a demonstration of the movement required and advice on maintaining correct practice. If standard upper limb position described by the protocol could not be maintained because of patient contractures, alternative positions were allowed. Trials were carried out with strong verbal encouragement asking the patients to provide maximal voluntary isometric contractions for 3 s. A rest period of about 30 s was respected between the trials.

Fig. 1 The MyoGrip device

The trials were considered valid or not by the physiotherapist relying on several factors (compensations, motivation, understanding, positioning, etc.). If the difference between two measurements was lower than 10% of the highest, the highest was accepted. If not, a subsequent measurement was made until two trials were within 10% with a maximum of five trials. The maximal value of all valid trials was kept for further analyses.

In two of the protocols (ULENAP and pre-Acti), two visits were performed within 14 days to assess the test–retest reliability of grip measurements.

Statistical analysis

MGS on the dominant side (defined as the writing/drawing hand) was analyzed using both absolute values (in kg) and normalized values (in % of predicted values for age). Equations of predictive models using chronological age were computed from previous data collected in healthy controls [4, 11, 22] as following: before the age of 17 years: MGS = $3.40 \text{ EXP}(0.1527 \times \text{age})$ and after the age of 17 years: MGS = $45.66 \text{ EXP}(-0.001 \times \text{age})$. Patients were classified according to their genotype, ambulatory status at the time of inclusion and glucocorticoid status. Test-retest reliability was assessed using an intraclass correlation coefficient (ICC) and a Bland-Altman representation.

Linear mixed effects models were used to assess trends in grip changes over time. Interactions were included separately in the model as fixed effects between time and ambulatory status, glucocorticoids use or mutations. Models were adjusted for age at inclusion.

Sample size was calculated by simulation study to determine the number of subjects required for a placebocontrolled clinical trial in which stabilization of the MGS in the treated group over one year should be detected, with an alpha risk of 5%, and a power of 80%. Grip values were simulated using linear mixed model included age, time, group and the interaction between age and group. We assumed no differences of grip value at baseline, so the coefficient value for the group where equal to 0. Beta parameters were simulated from a Gaussian distribution using results provided by the linear mixed model. When grip strength was expressed in kg, the stabilization meant that the grip evolution over time of treated patient was equal to the grip evolution of healthy controls. When grip strength was expressed in % predicted values, the stabilization meant that the change was 0%. We assumed than the variability of the treated group was the same than the DMD population presented in this study.

Analyses were performed using R 3.3.1 software (R Foundation for Statistical Computing, Vienna, Austria). Statistical significance was set at 0.05.

Results

Population description

A total of 202 subjects (5.0-28.7 years) were included in this cohort study (see Table 1). At baseline, 92 patients were ambulatory and 110 were non-ambulatory. With the exception of 13 subjects who had only one visit, the mean follow-up duration was 2.2 ± 1.6 years (range 0.04-6.53 years). A total of 977 measurement points was collected. Eighty-six ambulatory patients (93%) were treated with glucocorticoids, whilst only 53 non-ambulatory patients (48%) were. Fifty-nine patients had mutations amenable to exon skipping for exon 53, 28 for exon 44; 15 for exon 45, 25 for exon 51, 74 patients had other deletions (4 mutations amenable to exon skipping for exon 8, 3 for exon 43, 8 for exon 50, 3 for exon 52, 8 for exon 55 and 23 others) or other mutations (7 duplication, 2 insertion, 4 missense, 12 nonsense mutations), and 1 had an unknown mutation.

Grip strength measurement reliability

Test–retest reliability was assessed on 104 independent measurements (Fig. 2). The intraclass correlation coefficient was 0.977.

Grip strength change during the life of DMD patients

Absolute values of MGS increased by 0.23 kg/year on average in ambulatory boys and decreased by -0.34 kg/year in non-ambulatory patients (Fig. 3a). When expressed as percentage of predicted values for age, MGS decreased in

Fig.2 Test–retest reliability assessed using ICC $\left(a\right)$ and Bland–Altman plot $\left(b\right)$

Fig. 3 Grip strength change with age either expressed in absolute values (a) or in percentage of predicted value for age (b)

both groups (Fig. 3b). This decrease was significantly more important in ambulatory patients compared to non-ambulatory patients (-4.95% points per year vs. -2.53% points per year; p < 0.001).

Effect of *DMD* mutation, corticosteroid treatment and ambulatory status on grip strength

Glucocorticoids had a positive effect on muscle strength since the subjects without glucocorticoids were 6.3% weaker than patients treated with glucocorticoids (p < 0.001). However patients treated with glucocorticoids lost significantly more strength (significant difference of -2.84% points per year, p < 0.001).

Patients amenable to exon skipping 45, 51 and 53 were significantly weaker than patients amenable to exon skipping 44 (significant difference of 13.7%, 9.3% and 13.9%, respectively, p < 0.05). However the latter group lost significantly more strength per year (-5.8% points per year) than patients amenable to exon skipping 45 and 53 (significant difference of 3.0% points per year and 2.7% point per year, respectively).

Computation of the patient number needed for stabilizing grip strength during a therapeutic trial

Following the methodology specified in the "Methods", the number of patients per arm needed for a clinical trial is presented in Table 2.

Discussion

We showed that maximal grip strength expressed in percentage of predicted value counterbalances the cofounding effect of growth during childhood and can be used as continuous variable to measure the functional decline due to Duchenne muscular dystrophy across all stages of the disease. The analyses demonstrated the decrease of grip strength in a large population of DMD patients aged from 5 to 30 years compared to normal values. It is often suggested that upper limb function begins to deteriorate in DMD around the age of 9-12 years when assessed using scales [7, 8, 18]. This statement is partly due to the ceiling effect of scales. The use of high precision dynamometry and normalized values clearly demonstrates that grip strength decline can be captured at a younger age, as early as 5 years of age, as already underlined in the CINRG longitudinal study cohort [1] or other studies [19, 25]. The changes in grip strength described in the present study are perfectly in line with those recently published on a part of the cohort by Ricotti et al. [20]. However, the clinical meaningfulness of these changes has yet to be established; for example, upper limb functional limitations are most likely not clinically significant at 5 years of age, since DMD boys have sufficient strength for daily tasks, as well as full range of motion and ability to compensate for their strength deficit. In the context of a clinical trial, the relatively well-preserved muscles could offer the opportunity to study the effect of disease modifying drugs by way of measuring a stabilization (or even an improvement) in strength in response to therapies, where scales may suffer from a ceiling or a floor effect.

The age-dependence of MGS changes suggests that its decline was inversely proportional to age. The weaker the patients, the less strength they are prone to lose over again. Similar exponential-like decrease have already been observed for other variables. For example, forced vital

capacity, which is a variable generally expressed in percentage of predicted values, was also described as exponentially decreasing in DMD patients of equivalent ages [2, 10]. Outcome measures are generally presented in absolute values. The six-minute walk test (6MWT) has been the most widely used primary endpoint in therapeutic trials. The distance (in m) of the 6MWT is generally described as improving up to age of 7 due to maturation effect, before reaching a plateau and then declining [15]. This inversed U-shaped curve was also observed in MGS absolute values, where patients improved up to roughly 12 years and then decreased afterwards. A powerful way of minimizing the cofounding factors of growth and maturation is to express performance in percentage of predicted values for the considered variables [16]. This is particularly critical in children as they are growing [5].

In this report, we chose to express the model only in terms of age, since it avoids a possible error of measurement in a multicenter setting, but more powerful predictive equations were obtained in controls using hand circumference. Further studies should include a consistent estimate of stature such as height, ulnar length or hand circumference, which has been shown to be a strong predictive determinant of MGS [4]. It can be easily assessed even in wheelchairbound patients with contractures using strict measurement procedures.

Many factors influence muscle strength measurement and may act as confounding factors: genetics (mutation, genetic modifiers), developmental factors (chronological age, growth, pubertal status, stature), symptomatology (contractures, cognitive status), neural factors (compensation abilities, motor strategy, neural plasticity), behavioral factors (psychological status, motivation, self-esteem), environmental factors (social and cultural background) and obviously standards of care and assessors. These factors may explain, at least partly, the large variability between DMD subjects. Indeed, grip strength can be very heterogeneous among patients (see for instance Fig. 3 in Seferian et al. [21] or Figs. 3 and 4 in Connelly et al. [2]). The decline in MGS appeared however sensitive enough to detect a difference between exon 44 and exon 53 skippable patients, two genotypes that are known to be slightly less and more severe, respectively [23, 24].

The European Medical Agency reported in their guidelines that "for total evidence of clinical efficacy an effect on motor function should be supported by an effect on muscle strength" [3]. Indeed the main function of a muscle is to contract, to produce a mechanical force, to make the movement possible and translate it into an action. This function is primarily impaired in neuromuscular disorders. The assessment of strength is thus a direct measure of the muscle capacity and is a key feature to follow during the natural course of the disease but more importantly during the possible recovery of the muscle capacity to generate force. Due to the fact that the data were gathered from several protocols, there was unfortunately no common functional scale to use before MGS, which is a limitation of the present work.

The constant relative decline of MGS in both ambulatory and non-ambulatory DMD subjects, the absence of floor and ceiling effects, the good reliability of the measurements, the possibility to standardize data acquisition and finally the direct link between muscle function and strength production [21] makes maximal grip strength an attractive outcome measure for DMD trials. Further work is needed to quantify minimally clinically meaningful change using functional scales and demonstrate positive changes during interventional studies.

Acknowledgements Grip strength data in Duchenne muscular dystrophy (DMD) using the MyoGrip device were gathered through several natural history studies in several sites (London, Newcastle, Leiden, Nijmegen and Paris). The ULENAP study was sponsored by the Institute of Myology and funded by the Association Française contre les Myopathies. The pre-U7 study was sponsored by Genethon. This project was supported by the AFM (Association Française contre les Myopathies) and by ADNA (Advanced Diagnostics for New Therapeutic Approaches), a program dedicated to personalized medicine, coordinated by the Institut Mérieux and supported by research and innovation aid from the French public agency, OSEO. The pre-Acti study was sponsored by the Institute of Myology and funded by the Association Française contre les Myopathies. The iMDEX natural history study was sponsored by each participating center and funded by the Association Française contre les Myopathies. The SRP-4053 study was sponsored by Sarepta. No funders were involved in data collection, analyses or interpretation or in the preparation of this paper. They all gave their agreement for the use of data. In particular the authors wish to personally thank Geneviève Laforet and Elisabeth Thomson (from Sarepta) and Géraldine Honnet (from Généthon). This research was also supported by the NIHR Great Ormond Street Hospital Biomedical Research Centre. We thank the patients and their families for their participation in the studies used in the present meta-analysis. The grip strength data have been acquired in different protocols by several physiotherapists. We acknowledge the dedicated work of Gwenn Ollivier, Aurélie Canal, Charlotte Lilien and Stéphanie Gilabert (Paris), Merel Jansen, Maaike Pelsma and Anke Langelaan (Nijmegen), Menno van der Holst (Leiden), Vic Selby and Jordan Butler (London), Michela Guglieri, Alexander Murphy and Anna Mayhew (Newcastle). We are also grateful to Amélie Moraux and Pauline Hivert for the management of the MyoGrip database and to Simone Birnbaum for thorough proofreading of the manuscript and text improvement. The authors would like to pay tribute to the memory of Joana Pisco Domingos, suddenly deceased in early January 2018.

Author contributions Designing the studies: J-YH, VS, FM, TV, LS. Methodology of grip strength measurements: J-YH, VD. Acquisition of the data: EN, IG, VS, FM, VR, TV, AS, TG, LS. Compliance with ethical standards

Conflicts of interest Jean-Yves Hogrel is the inventor of the Myo-Grip device (patented). Erik Niks reports consultancies for BioMarin, Summit and WAVE for which reimbursements were received by the LUMC. Imelda de Groot has received consulting and education fees from PTC Therapeutics, Santhera, Biomarin/Prosensa. Volker Straub received speaker honoraria from Sanofi Genzyme and has participated in advisory boards for Audentes Therapeutics, Biogen, Bristol-Myer Squibb, Exonics Therapeutics, Italfarmaco S.p.A., Pfizer, Roche, Sanofi Genzyme, Sarepta Therapeutics, Summit Therapeutics, UCB, and Wave Therapeutics. He has research collaborations with Ultragenyx and Sanofi Genzyme. Francesco Muntoni has received consulting fees from Biogen, Italfarmaco, Pfizer, PTC Therapeutics, Roche, Sarepta Therapeutics, and Wave Therapeutics; and is involved as Chief Investigator in the EUFP7 / Sarepta Therapeutics funded clinical trial (SKIP NMD study, EU FP 7 No. HEALTH-F4-2012-30537) and principal investigator in the Sarepta Therapeutics funded study ESSENCE. He is also supported by the National Institute of Health Research Biomedical Research Centre at Great Ormond Street Hospital for Children NHS Foundation Trust, and University College London. The support of the MRC Neuromuscular Centre Biobank and of the Muscular Dystrophy UK is also gratefully acknowledged. Thomas Voit serves on scientific advisory boards for Constant Pharmaceuticals and Metriopharm; he is a co-founder of AlterGene; he serves or served as a consultant for Biomarin, Biophytis, Evox, Capricor, Catabasis, Debiopharm, Italfarmaco, Santhera, Sarepta, Servier, Solid and Summit. Teresa Gidaro has served on scientific advisory boards for PTC and Ultragenyx. Laurent Servais has received consulting fees from Roche, Biogen, Avexis, Cytokinetics, Sarepta, Biomarin, Santhera, Servier, Biophytis and Dynacure. He is coordinating natural history studies funded by Valerion, Dynacure and Roche. The other authors report no disclosure.

Ethical approval All studies have been approved by the appropriate ethics committee and have, therefore, been performed in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki and its later amendments. All patients or legal guardians for patients younger than 18 years of age gave written informed consent prior to participation in the studies.
