Abstract

To mount an adequate immune response against pathogens, stepwise mutation and selection processes are crucial functions of the adaptive immune system. To better characterize a successful vaccination response, we performed longitudinal (days 0, 5, 7, 10, and 14 after Boostrix vaccination) analysis of the single-cell transcriptome as well as the B-cell receptor (BCR) repertoire (scBCR-rep) in plasma cells of an immunized donor and compared it with baseline B-cell characteristics as well as flow cytometry findings. Based on the flow cytometry knowledge and literature findings, we discriminated individual B-cell subsets in the transcriptomics data and traced over-time maturation of plasmablasts/plasma cells (PB/PCs) and identified the pathways associated with the plasma cell maturation. We observed that the repertoire in PB/PCs differed from the baseline B-cell repertoire e.g., regarding expansion of unique clones in post-vaccination visits, high usage of IGHG1 in expanded clones, increased class-switching events post-vaccination represented by clonotypes spanning multiple IGHC classes and positive selection of CDR3 sequences over time. Importantly, the Variable gene family-based clustering of BCRs represented a similar measure as the gene-based clustering, but certainly improved the clustering of BCRs, as BCRs from duplicated Variable gene families could be clustered together. Finally, we developed a query tool to dissect the immune response to the components of the Boostrix vaccine. Using this tool, we could identify the BCRs related to anti-tetanus and anti-pertussis toxoid BCRs. Collectively, we developed a bioinformatic workflow which allows description of the key features of an ongoing (longitudinal) immune response, such as activation of PB/PCs, Ig class switching, somatic hypermutation, and clonal expansion, all of which are hallmarks of antigen exposure, followed by mutation & selection processes.

Keywords: B-cell receptor repertoire; Tdap vaccine; pertussis; single cell; vaccination

Introduction

The adaptation of the immune system to recognize antigenically distinct epitopes of pathogens is a critical feature of the antibody (Ab) -mediated immunity in response to infection/vaccination. Abs are products of terminally differentiated B cells, plasma cells (PCs), and are the secreted forms of B-cell receptors (BCRs). Generation of a highly diverse BCR repertoire (BCR-rep) starts during precursor B-cell development in bone marrow, where developing B cells assemble immunoglobulin heavy (IGH) and light chain genes in the process of V(D)J recombination. B cells with a functional BCR leave the bone marrow and are ready to recognize antigens in the peripheral immune system. Following antigen recognition, the BCR undergoes affinity maturation in the germinal centers (GCs) through introduction of somatic hypermutations (SHM) and subsequent selection processes for B cells with high-affinity BCR [1]. The introduction and subsequent selection of SHM are critical steps in raising the appropriate immune response. Typically, through positive selection, SHM accumulate in so called complementarity-determining regions (CDRs) because CDRs are in direct contact with the antigen, while SHM in the framework regions (FWR) are less frequently selected, because FWRs are responsible for maintaining receptor structure. Additionally, B cells optimize their effector functions by exchanging the initial C μ constant region by other downstream IGH constant regions. This process is known as class-switch recombination (CSR). Memory B cells that have recognized pathogen/antigen circulate through the peripheral lymphoid system, differentiate into plasmablasts and re-enter bone marrow to become long-lived Ab-producing PCs. The immune response to a booster vaccination or a re-encounter of the same antigen would lead to the use of pre-existing Abs as the first line of defense [2]. The encounter with an antigen will initiate the processes of SHM and affinity maturation where new Abs are generated from the pool of the pre-existing memory B cells [3,4]. Using flow cytometry, we have recently shown that in booster vaccination settings (Boostrix), an increase in circulating PC numbers, associated with their phenotypical maturation, occurs as early as five days post-vaccination, with a peak in expansion and maturation at day seven post-vaccination [5]. However, the dynamics of the over-time changes in the BCR-rep after Boostrix vaccination in humans are not known yet. Therefore, we performed longitudinal measurements and analysis of single-cell transcriptomics and single-cell BCR-rep (scBCR-rep) in PCs derived from an individual vaccinated with a Tdap Booster vaccine (Boostrix®, GlaxoSmithKline), and compared them with the total BCR-rep at baseline. Along with understanding the dynamics of scBCR-rep after Boostrix vaccination, with this pilot study, we aimed to assess the differences between the flow cytometry and single-cell transcriptomics data at the level of protein vs. transcript expression level and develop a bioinformatics workflow to identify key features of an ongoing (longitudinal) immune response. Furthermore, we also tracked the footprints of the selection processes e.g., V(D)J usage, level of SHMs in FWRs and CDRs and CSR events in B-cell clonotypes to understand the immune responses in a booster vaccination.

As the Boostrix vaccine contains multiple antigens i.e., diphtheria toxoid (DT),

tetanus toxoid (TT), three *Bordetella pertussis* proteins i.e., filamentous hemagglutinin (FHA), pertactin (Prn) and pertussis toxoid (PT), and aluminum hydroxide as an adjuvant [6], we obtained receptor repertoire information against all components of the vaccine. Although it is known that majority of PCs in the response peak at day 7 (d7) are Ag-specific [7,8], we aimed to dissect the immune response against each component. This was, however, subjected to the known pool of Abs against the antigens of Boostrix vaccine. Knowing limitations of the available anti-toxoid Abs for toxoids in vaccine, we developed a method to search the known Ab CDR3 sequences for these vaccine components in our data.

Here, we have analyzed the longitudinal single-cell transcriptomics and scBCR-rep data in PCs derived from an individual vaccinated with Boostrix vaccine and compared them with the total B cells and/or plasma cells at baseline. Using transcriptomics data, we have identified additional membrane markers for flow cytometry that can be used to identify the B-cell subtypes and maturation of plasma cells. With the scBCR-rep data, we have clustered functionally similar receptors and assessed different components of the repertoire for associations between visits and to baseline. Importantly, we found BCRs associated with the vaccine components in scBCR-rep data.

Methods

Inclusion Criteria and Informed Consent from the Subject

The donor used in this study was a 28-year-old female, who was recruited as one of 10 healthy adults in a vaccination study where volunteers received Boostrix and wherein their immune responses were monitored over-time by means of flow cytometry (registration number: P16-214, EUDRACT: 2016-002011-18). This longitudinal study aimed at understanding the (Ag-specific) cellular immune responses post-Boostrix vaccination and was approved by the Medical Ethics Committee Leiden-Den Haag-Delft. Inclusion and exclusion criteria were previously published [5]. In short, the donor had to be generally healthy, had completed a vaccination schedule according to the Dutch National Immunization program (www.rivm.nl/en/national-immunisation-programme; accessed on 31 August 2020) and had no known or suspected exposure to pertussis infection nor vaccination in the past 10 years. She also provided an informed consent prior to the inclusion. The individual was selected for the current single-cell study as she had a representative increase in plasma cells at the peak of the plasma cell response (i.e., day 7 (d7)). EDTA-blood samples for single-cell transcript sequencing were collected at baseline and d5, d7, d10 and d14 post-vaccination, which based on the parent study, corresponded to the plasma cell expansion (d5-d10) and contraction of plasma cell response [5] (**Figure S1**). The sequencing of the samples of only one individual were performed as a pilot study to optimize the pipeline to sort cells from the frozen samples, to make comparative assessment of the flow cytometry and transcriptomics data and to develop a pipeline for downstream processing the BCR-rep data and identify toxoid specific BCRs from total B cells.

High Throughput B-Cell and Plasmablast/Plasma Cell Sorting

Prior to the sort, 78.2 million PBMCs from five different time-points were individually (per time-point) stained with an Ab cocktail for surface markers for 30 min at RT in the dark (CD19 BV786, CD24 BV650, CD27 BV421, CD38 Per-CP-Cy5.5), followed by a live/dead staining (Zombie NIR Fixable Viability kit, Biolegend) according to the manufacturer's protocol. Next, samples were prepared for multiplexing according to the protocols provided on the 10x Genomics website (www.10xgenomics.com; accessed on 9 January 2019). In short, Fc block was added and after a 10 min incubation at 4 °C, unique cell hashing Abs (10x Genomics) were added to each sample separately (per time-point). After incubation for 20 min at 4 °C, cells were washed three times and resuspended in PBS. Next, all post-vaccination samples were pooled and sorted on a high-speed cell sorter (BD FACSAria III, BD Biosciences at the flow cytometry core facility of LUMC) using an 85µm nozzle and a pressure of 45PSI, while the baseline sample was sorted separately, but in the same collection tube, to ensure an enrichment of plasmablasts/plasma cells (PB/PCs) in the sorted sample. Cells were collected in a BSA-coated Eppendorf tube filled with an RPMI + 10% FCS solution to avoid excessive cell loss. At baseline, the first 10,000 total CD19+ B cells were sorted, and after adjusting the sorting gate to exclusively sort PB/PCs, another 1201 CD19+CD38++CD24+CD27+ PB/PCs were sorted. For subsequent visits, all available PB/PCs were sorted (11,051 cells). In total, we sorted 22,252 cells. Directly after the sort, samples were spun down and resuspended into the recommended volume (RPMI + 10% FCS). Further sample processing took place at the Leiden genome technology center (LGTC) in the LUMC according to the 10x Genomics protocols (**Figure S1**).

10x CITE-Seq Transcriptomics and scBCR-Rep Sequencing

Nearly 22,000 B cells enriched in PB/PCs from different time-points were processed into single cells in a Chromium Controller (10x Genomics) (**Figure S1**). During this process, individual cells were embedded in Gel Beads-in-Emulsion (GEMs) where all generated cDNAs share a common 10x oligonucleotide barcode. Reverse transcription PCR and library preparation were carried out under the Chromium Single Cell 3' v3 protocol (10x Genomics) per manufacturer's recommendations. After amplification of the cDNA, a 5' gene expression library and paired heavy and light chain library were generated from cDNA of the same cell using Chromium Single Cell VDJ reagent kit (scBCR-rep library; v1.1chemistry, 10x Genomics). After library preparation, quality control was performed using a bioanalyzer (Agilent 2100 Bioanalyzer; Agilent Technologies). The libraries were sequenced in the NovaSeq6000 sequencer (Illumina) using the v1.0 sequencing reagent kit (read length: 2 × 150 bp).

Unsupervised Clustering of Single-Cell Transcriptomics Data

The raw sequencing data from different visits were processed using Cell Ranger (v3.1.0) against the GRCh38 human reference genome with default parameters. Single-cell RNA-seq data were processed in R with Seurat (v3.2.3) [9]. Raw UMI count matrices for both expression and hashtags oligos (HTO) generated from

the Cell Ranger 10x Genomics pipeline (<https://www.10xgenomics.com/>; accessed on 27 August 2019) were loaded into a single Seurat object. Cells were discarded if they met any of the following criteria: percentage of mitochondrial counts >25; the number of unique features <100 or >5000. Furthermore, mitochondrial genes, non-protein-coding genes, and genes expressed in fewer than 3 cells were discarded. Moreover, the immunoglobulin V genes were removed from the counts for clustering analysis. The scaled counts of the constant genes were added to the metadata of the Seurat object. We used MULTISEQDemux [10] with default parameters to demultiplex the data to independent visits (corresponding to HTO1-HTO5 tags) and eliminated doublets and negatives among the cells (**Figure S2**). We found a few T cells (~20–30 cells) in our data which clustered separately and we removed them from further analysis.

After retaining 5010 singlets, we log normalized the gene counts for each cell using the ‘NormalizeData()’ function of Seurat with the default parameters. The normalized data were scaled again using ‘ScaleData()’. The G2M and S phase scores were regressed out from the Seurat object. Principal component analysis (PCA), selecting the 10 most varying principal components, and t-distributed stochastic neighbor embedding (tSNE) dimension reduction were performed. A nearest-neighbor graph using the 10 dimensions of the PCA reduction was calculated using ‘FindNeighbors()’, followed by clustering using ‘FindClusters()’ with a resolution of 0.6. FACS-like plots were generated using transcript average cell scoring implemented in ‘TACSplot()’ [11].

Differential Gene Expression Analysis

For comparisons between expression values, the Seurat function ‘FindMarkers()’ was used with the ‘Wilcox method’. Cell type markers were obtained using the ‘FindAllMarkers()’ function with a Wilcoxon signed-rank test. The fold changes of the mean expression level of genes between the selected cell populations were calculated. The pathway analysis of the relevant genes was performed using ‘ClueGO’ [12].

Identification of V(D)JC Genes in the Reconstructed BCRs

Demultiplexing, gene quantification and BCR contig and clonotype assignment were performed using the Cell Ranger 3.0.2 V(D)J pipeline with GRCh38 as reference. In order to get the BCR of a single cell, we obtained high-confidence contig sequences for each cell and kept the contigs with productive BCR rearrangements. The assembled filtered BCRs from 6437 cells were submitted to IMGT HighV-Quest for the V(D)J annotation. The constant gene annotation of the BCRs was obtained from the Cell Ranger output. The usage of constant gene in this individual was identified from the single-cell data and was compared with the constant gene usage identified by the flow cytometry. All chains (single, pairs, threes or fours) were retained. Of 6437 cells with BCRs, 4051 single cells had one heavy chain recorded in the Seurat object. The repertoire analysis was performed on both the sets (6437 and 4051 cells) and the discussed set is implicitly mentioned in the text or figure legends. In case two or more in-frame/productive

heavy chains were recorded from one cell, both the chains were included in the repertoire analysis.

Identification of B-Cell Clonotypes

Multiple files obtained from the IMGT HighV-Quest were combined using an in-house Python script. The B cell clonotypes were identified with the same V family, J gene, and 80% nucleotide identity in IG heavy chain CDR3 as computed by Levenshtein distance {Python}. As V gene assignment might be flawed by the assignment methods, we used the V family to call clonotypes which avoids inaccurate grouping of the clones in the first place. Also, a comparative assessment was performed of the clonotypes obtained when using V genes versus V family in assigning B cell clonotypes.

Analysis of scBCR-Rep and Clonotypes

The Circos plots of VJ usage were made using circlize {R}. To plot identified clonotypes, IGHC usage, class-switching events and CDR3 length usage, ggplot2 {R} was used. We used bcRep {R} [13] to plot the amino acid usage in the amino acid sequence of the junction. BCellMA {R} [14] was used to plot the replacement amino acid mutations from IMGT HighV-Quest output tables. Clonal lineages were built using alakazam [15] and plotted using igraph {R}. The clonal lineages were built based on the SHMs introduced in the V gene sequence. The V genes were compared to the germline V gene in the IMGT database and the number of mutations in the clonal group was used to build these lineages. In case two different mutation lineages were detected in a clonal group and an intermediate BCR was missing, the tool alakazam incorporated an inferred node suggesting a missing BCR that could not have been sampled and/or sequenced.

3.3

Query Tool to Identify Anti-Toxoid BCRs

The currently profiled BCRs comprise of all the PB/PCs raised in response to the vaccine which comprises of multiple components. To identify the contribution of each component of the vaccine, we developed an in-house tool using Python. To show its functionality, junction sequences related to anti-TT, anti-DT, anti-FHA, anti-Prn and anti-PT were searched in the literature. We could only identify the CDR3 sequences for anti-TT, anti-DT and anti-PT. These sequences were searched in the Boostrix-specific BCR-rep obtained in this study. The search was not only performed based on the percentage identity, but a parameter of length flexibility was also incorporated; i.e., the search space will include junction sequences that are longer or shorter by a user defined length. The sequence similarity is calculated based on the Levenshtein distance of the junction sequences.

Results

Single-Cell Transcriptome Landscape of the Cells from a Vaccinated Individual

Majority of the PB/PCs Derived from d5 and d7 Post-Vaccination

We measured the transcriptomics and BCR-rep data at the single-cell level from the longitudinal samples obtained from an individual following Boostrix vacci-

nation. After applying quality checks to the transcriptomics data from 10,000 total CD19+ B cells and 12,252 CD19+CD38++CD24+CD27+ PB/PCs from five pre-defined time-points (**Figure S1**), we obtained 5010 singlets (**Figure S2**). Unsupervised clustering using Seurat distinguished seven different cell clusters based on their transcription profile (**Figure 1A**). CD19, CD38, CD24 and CD27 markers used to define the cells by flow cytometry allowed discrimination between B cells (**Figure 1A**; Clusters B1-B3) and PB/PCs (**Figure 1A**; Clusters P1-P4). Based on the tag mapping we could identify the sampling time-point of individual cells. The highest number of cells was obtained from d0 when both total B cell and PB/PCs were sorted. At follow-up visits, more PB/PCs were obtained at d5 and d7 and clearly less at d10 and d14 (**Figure 1B** and **Figure S2B**). This reflected the number of sorted cells (**Figure S1B**), but mostly post-vaccination fluctuations in the number of PB/PCs (**Figure S1C**), which were also observed in the flow cytometry data obtained from this donor previously [5].

Proliferating Cells Are Clustered in One Cluster

Despite having regressed out cell cycle influence, the P4 cluster separated based on the expression of the cell cycle genes (**Figure 1C**). A majority of the cells in all the clusters, except P3 and P4, were in G1 with a few cells in S phase, whereas P3 and P4 clusters were heavily comprised of the cells belonging to S and G2M phase (**Figure 1C**), suggesting that most proliferating cells are clustered in P4. The cells present in G1 phase are the mature PB/PCs deemed to produce Abs which are mostly present in P1 and P2 clusters.

B1-B3 Clusters Correspond to Naive, Memory and Activated Memory B Cells, Respectively

The B-cell clusters i.e., B1-B3 were assigned individual identities based on the differentially expressed genes among these clusters and the classical markers and/or literature. The B1 cluster expressed classical markers of naive B cells i.e., IGHD, CXCR4^{high} [16] and FOXP1 [17] (**Figure 1D**). Cluster B2 was defined as memory B cells based on overexpressed of unique markers e.g., BANK1, REL. The genes BCL3 and LTB, that promote Ab production, were also highly expressed in cluster B2 [18]. The SOX5, ZBTB32 are markers for activated memory B cells which were also representative markers for cluster B3, hence the 124 cells in cluster B3 were identified as activated memory B cells [19]. The decreasing expression of CXCR4 marker from naive to memory to activated memory B cells was observed in clusters B1 to B3, which was also mentioned in the similar subsets identified from an influenza vaccination study [19]. Overall, we could discriminate between naive B cells (cluster B1), memory B cells (cluster B2), activated memory B cells (cluster B3) and PB/PCs (clusters P1-P4) based on markers unique to these cell types (**Figure 1A, D**).

Flow Cytometry Guided Plasma Cell Maturation in the Single-Cell Transcriptome

Staging of PB/PCs Based on Flow Cytometry Markers

Previously, we used longitudinal flow cytometry data from 10 vaccinated donors

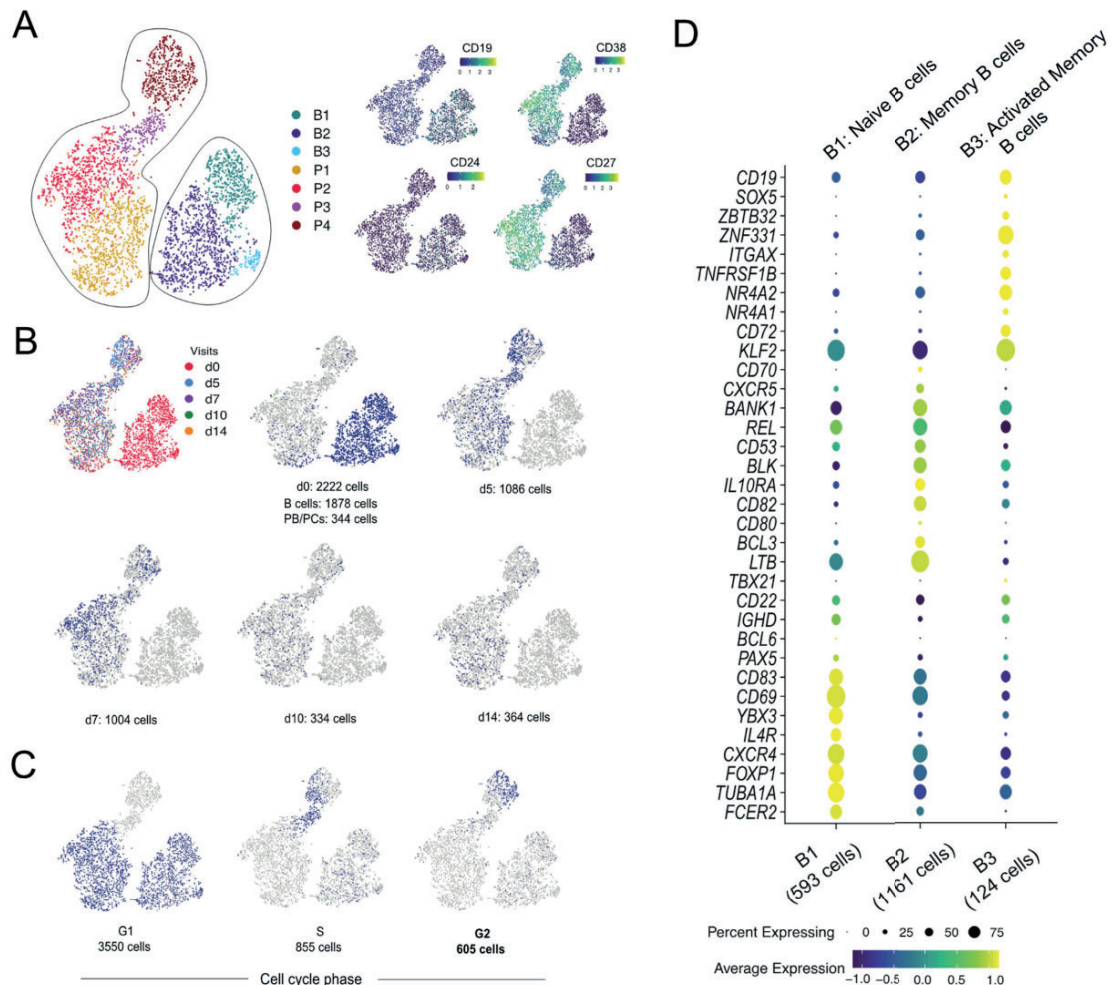

Figure 1. Identification of B-cell subpopulations by single cell-transcriptomics analysis. (A) The clusters of cells are represented on a tSNE plot based on the highly variable genes. The clusters are named as B1-B3 for B cells and P1-P4 for PB/PCs. The expression of the markers used for sorting the cells in the study is plotted on the tSNE plot. High expression of CD38 and CD27 marks the clusters P1-P4 as the PB/PCs. (B) Plotting tag information on the tSNE plot. The cells are assigned to each visit and cells at d0 are assigned to B cells and PB/PCs based on their location in B1-B3 and P1-P4 clusters, respectively. (C) Visualizing cell cycle scores on tSNE plot. G1, S and G2M cell-cycle scores are represented on the tSNE plot where P3 and P4 clusters comprise of S and G2M phase cells. (D) Dot plot of the gene markers used for identifying the B-cell subpopulations. B1: Naive B cells; B2: Memory B cells; B3: Activated memory B cells.

to establish how expression of selected cell surface markers changes during maturation of PB/PCs [5]. To visualize the plasma cell maturation in the here studied donor, the PB/PCs data from days 0, 5, 7, 10 and 14 were merged in the Infinicyt software (Infinicyt™ Software v2.0, Cytognos) and the maturation was defined by the downregulation of CD20 and upregulation of CD138 (**Figure 2A** left panel). The most mature cells exhibited CD20-CD138+ phenotype. Then we traced changes in expression of four additional markers i.e., CD19, CD27, CD62L, and CD38. Based on the expression of all six markers, we drew new maturation pathways and divided it into six continuous maturation stages (**Figure 2A** right panel). Similar to flow cytometry staging, after removing B cells, PB/PCs

were clustered based on all the genes and arranged with phenotype ranging from CD20+CD138- (less mature) to CD20-CD138+ (most mature) (**Figure 2B**). However, the cells from different clusters were mixed and the maturation based on P1-P6 clusters could not be drawn. Therefore, we clustered the PB/PCs again based on the expression of only 6 genes SELL (CD62L), TNFRSF7 (CD27), SDC1 (CD138), ADPRC1 (CD38), MS4A1 (CD20) and B4 (CD19)) and used the expression of CD20 and CD138 to align the clusters with the maturation pathway of the PB/PCs. Herein, based on the maturation pathway defined by CD20 and CD138 markers, a trajectory from the blue-colored clusters (Pa1) to the dark red ones (Pa10) can be drawn (**Figure 2C**). Based on the maturation of clustered cells the staging of the PB/PCs was performed from Pa1-Pa10 and the expression of other markers was assessed (**Figure 2D**).

Pathways and Additional Membrane Markers Identified in Relation to the Maturation of PB/PCs

Based on the 10 clusters/stages of the plasma cell maturation, we identified additional markers that might be changing during the maturation of the PB/PCs (**Figure 2E**). Genes with similar expression to the six maturation markers were selected from the single-cell transcriptomics data (**Table S1; Figure 2E**). The HLA locus-specific genes were not included in the analysis. Several of these genes are involved in the regulation of immunoglobulin production, molecular mediation of immune responses, N-glycosylation, antigen processing and presentation, protein folding and cytokine production (**Figure 2F**). The majority of these pathways directly suggest the role of these genes in the Ig secretion, post-translational modifications to ensure correct folding of the proteins and henceforth an optimum response of the immune system to the vaccines. This is in line with the preparation for immunoglobulin secretion, which is the major role of most mature PB/PCs.

Characteristics of V(D)J Usage over Time upon Vaccination

Identification of Ig Heavy and Light Chains in Majority of the Sequenced Cells

Additional to transcriptomics profiling, we measured the BCRs of the cells from the longitudinal samples obtained from an individual after Boostrix vaccination. The barcode mapped BCR information for each cell was obtained from the Cell Ranger output. We filtered out the unproductive rearrangements and could map at least one heavy or light chain for 4175 cells (**Figure S3A**). No chain was recorded for 835 cells (of which 818 cells were collected at do) (**Figure S3A**), most likely owing to the low expression of BCR in non-plasma cells. We also observed that the cells comprised multiple chains varying from three to five heavy and/or light chains (~8%). Therefore, we filtered out additional chains that were supported by a low number of reads as compared to the other chains from the same cell. In case multiple productive chains were supported by similar number of reads, we included them all in our analysis. After filtering, we found varying chain numbers (1, 3 or 4 chains) mostly for B cells identified at do (**Figure S3A**), which partly could be related to the low expression of BCR or possible doublets. The BCRs with 3 or 4 chains comprised of completely different V, D, J and C genes for

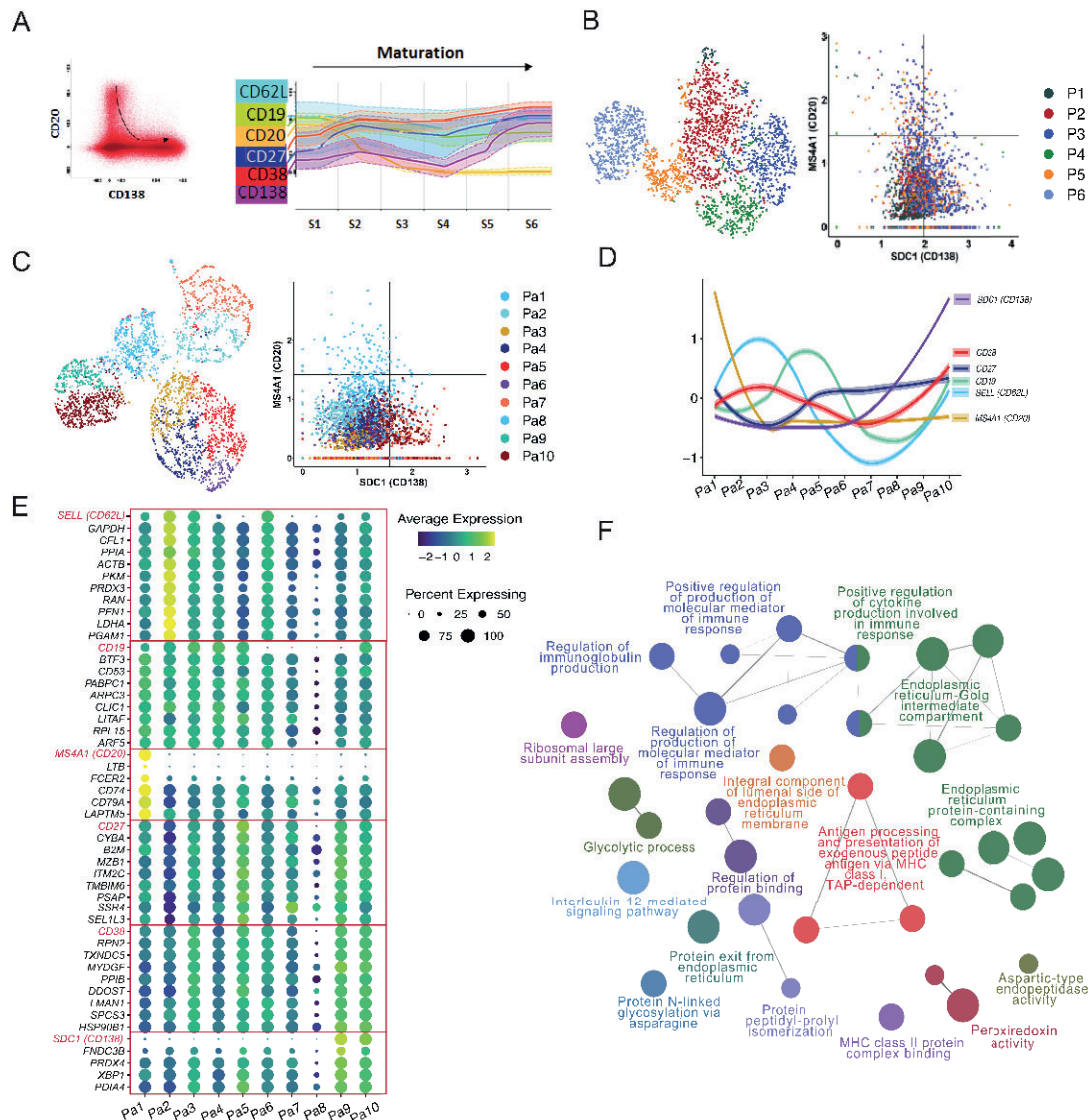

Figure 2. Plasmablast/plasma cell maturation using flow cytometry and single-cell transcriptomics data over time following vaccination. (A) Flow cytometric evaluation of cell surface markers in maturing PB/PCs. Plasma cell maturation pathway was drawn in the Infinicyt software based on the surface expression of CD20 and CD138. The least mature PB/PCs were defined as CD20+CD138- and the most mature as CD20-CD138+. Dot plot in the left panel shows all PB/PCs from the same donor and time-points used in the sequencing, and black arrow indicates the direction of plasma cell maturation. Each dot represents one cell. Subsequently, the entire maturation pathway was divided into 10 maturation stages (S1–S6), for which expression of additional cell surface markers was evaluated (right panel). (B) FACS-like plot to arrange PB/PCs clusters P1–P6 in the maturation pathway defined by the expression of CD20 and CD138. (C) Redefining stages of PB/PCs in single-cell transcriptome data using six markers pre-selected based on flow cytometry. The PB/PCs were clustered using six pre-defined maturation markers and FACS-like plotting is used to stage the plasma cell clusters based on the maturation pathway. Ten clusters i.e., Pa1–Pa10 were obtained. (D) The spaghetti plot of all six markers visualized after staging the PB/PCs. (E) Additional maturation markers identified using single-cell transcriptomics data based on the Pa1–Pa10 plasma cell clusters and corresponding stages. Genes following similar expression patterns were identified using the TACSplot function. (F) The important pathways identified based on the top 20 similar genes to each of the six maturation genes. The GO terms based on biological processes, molecular pathways, cellular components, and immunological processes were merged. The pathways with <0.05 corrected p values were selected for visualization.

both heavy and light chains, which might be related to the doublets that could not be removed in the filtering steps or the production of multiple chains in B cells [20]. For further comparisons in the manuscript, the BCRs from do B cells and PB/PCs were considered independently and post-vaccination BCRs were compared with do PB/PCs. Also, the expression of BCRs in B cells for both heavy and light chains was lower as compared to plasma cells.

Cells with Different IGHV and IGHJ Are Dominant at Different Time Points

The single cells with paired heavy and light chain information revealed preferential pairing between IGHV genes and IGKV1 and IGKV3 gene families (**Figure S3B**). IGLV genes mostly belonged to the IGLV1, IGLV2 and IGLV3 gene families. Also, over time, IGKV1, IGKV3, IGLV1, IGLV and IGLV3 gene families remained the most abundant, with minor variations in the usage which can be due to the limited number of cells or expansion of individual clones. However, no strong selection for a particular light chain was observed. On the contrary, we did observe changes in the usage of the IGHV genes over time (**Figure S3B**). Overall, the IGHV3 was the most used gene family, however, the usage of IGHV1, IGHV2, IGHV4 gene families increased in PB/PCs collected at d5 and d7 (around the peak of plasma cell response). To better understand the dynamics of the gene usage in IGH chains, we looked into the V(D)J gene usage. We found that IGHD3 genes were used the most over all time-points, whereas the usage of IGHV and IGHJ genes changed over time (**Figure S3C**). We observed that the increased usage of IGHV1, IGHV2, IGHV4 gene families was accompanied by an increased usage of IGHJ2, IGHJ3 and IGHJ6 genes post-vaccination.

IGHV3 and IGHJ4 Genes Predominant in do PB/PCs

As we observed increased usage of several IGHV and IGHJ gene families, we examined the usage of IGHV and IGHJ gene families in all cells across different visits at baseline and post-vaccination. We observed more restricted scBCR-rep in do PB/PCs as compared to do B cells (**Figure S3D**). While 55 unique of 158 VJ pairs were observed in do B cells, only 16 unique usage of 118 VJ pairs were present in do PB/PCs. The IGHV3-23 and IGHJ4 were the most used pairs in both do B cells and PB/PCs. The majority of the recombination events observed in do B cells used IGHV1, IGHV3, IGHV4, IGHV5 families recombining with IGHJ4, however, it was highly selective in do PB/PCs, i.e., the IGHV3 family genes and IGHJ4 gene were used the most.

Few Clonotypes Expand with Delay at d10

While comparing the PB/PCs from post-vaccination visits to do PB/PCs, we observed that the overall diversity increased at all the time-points post-vaccination (**Figure 3A**). We observed 50 and 65 new VJ pairs at d5 and d7 post-vaccination, respectively. Despite comparable numbers of sorted PBMCs and plasma cell counts at d10 and d14, we observed 24 new VJ pairs at d10 post-vaccination as compared to 35 new VJ pairs used at d14. Overall, we observed high usage of the IGHV3-23 gene and the IGHV4 gene family at all time-points including baseline. A clear expansion of IGHV1 and IGHV4 family genes especially IGHV1-2, IGHV1-

Figure 3. VJ gene usage in PB/PCs from all the post-vaccination visits relative to baseline. (A) Circos plot of VJ gene usage in PB/PCs from all the post-vaccination visits relative to baseline. Each ribbon represents a specific pairing between V and J genes, and the ribbon width represents the confidence bounds of the plotted data using the LOESS method. Ribbons color shows no change (yellow) or expanded links (dark blue) or new recombination events (red) as compared to do PB/PCs. (B) Heatmap plot of VJ gene usage in PB/PCs from all the post-vaccination visits.

18, IGHV3-33, IGHV4-39, IGHV4-31 gene can be observed around the peak of plasma cell expansion (**Figure 3A**; d5, d7 and d10). IGHV5-51 usage was also observed to be expanding at d10. The expansion of selected few V(D)J genes at the later time-points suggested the expansion of few clones with a delay. When comparing the relative usage of IGHV and IGHJ genes between visits post-vaccination, we observed that the usage of majority of the genes is comparable between visits with few exceptions, for example, the usage of IGHV1-69 increased at d5 and d7 post-vaccination (**Figure 3B**). Furthermore, IGHV1-2 and IGHJ3 were used the most at d5, whereas IGHV1-2 and IGHJ4 were used at d7, while at d10 and d14 the usage of IGHV1-2 was minimal.

Constant Gene Usage over Time upon Vaccination

IGHG1 Constant Gene Predominant at the Peak of the PB/PCs

Assessment of the constant gene usage helps in understanding the raised effector function post-vaccination. To identify the usage of the constant genes in the profiled BCRs, we grouped the receptors based on the constant genes.IGHM was the most used constant chain in do B cells (**Figure 4A**), followed by IGHD. It was in line with the abundance of naive/pre-germinal center B cells in the pre-vaccination scBCR-rep. However, IGHA1 was the most used constant gene in the do PB/PCs (**Figure 4A**). The composition of the constant chains changed after vaccination and IGHG1 became the most used chain. The percentage of cells utilizing IGHA1 decreased at the peak of the plasma cell response i.e., d5 and d7, but at d10 and d14 returned to the levels comparable to baseline. The usage of IGHD was negligible in the PB/PCs post-vaccination. On the other hand, IGHM usage reduced at the peak of PB/PCs response which returned to original levels at d14. We observed a similar trend in the flowcytometry data, wherein the 67% of PB/PCs expanded at d7 was IgG1+ and the relative usage of IgA1 was reduced (**Figure 4B**). The IGHD expression was relatively low in the single-cell data limiting identification of the IgM+IgD+ B cells, which we could indeed identify in the flow cytometry data (data not shown). With the paired chain information from single cells, we observed that the IGKC gene was the most used gene followed by IGLC2 in all the post-vaccination visits. The high usage of the IGKC gene is in line with our previous results specifying high usage of IGKV gene families (**Figure 4C**). Interestingly, in do PB/PCs, IGLC1, IGLC2 and IGLC3 genes were used more frequently than other IGLC genes.

BCR Clonotypes over Time upon Vaccination

Identification of Clonotypes Based on V Family Grouping

The BCRs were clustered into clones/clonotypes with a slight deviation from the classical definition of clonotypes; instead of genes, we used V family and J gene for grouping. Irrespective of the definition used, results of the clustering were highly similar (rand index of 0.99). The differences in the number of clusters were caused by the fact that several singletons clustered with other singletons with similar BCRs when the V gene definition was relaxed by V family (**Table S2**). Of 3334 clonotypes, 662 clonotypes could not be assigned any visit, 575 of which were singletons (8 clones with >10 BCRs; the largest clone comprises 129

Figure 4. The dynamics of heavy and light constant gene usage in the BCRs over different time-points pre- and post-vaccination. (A) Usage of IGH constant genes in single-cell BCRs over time. The PB/PCs and B cells at the d0 are considered separately. (B) Over time usage of constant genes in the PB/PCs as identified by flow cytometry (based on membrane and intracellular Ig expression). (C) The usage of heavy and light constant genes across different visits. The numbers in the heatmap are the number of chains using a given pair and the colors are ranged based on the scaled counts for each visit.

BCRs). Overall, 936 of 3334 clonotypes had at least 2 cells. 369 of 936 clonotypes were shared between at least two visits of which 145 clonotypes had cells present on d0. For the 4051 cells derived from the known visits and with a rearranged productive heavy chain, **Figure 5A** shows the origin of the top 30 (449 BCRs) of 145 (2075 BCRs) clonotypes. The largest clone comprised of 46 B cells and was present in all visits but d14 (**Figure 5A**; C115). However, 30 additional B cells belonged to the same clonotype, but could not be assigned any visit (**Figure S4A**; the top second clone). The clonotype C115, consisting of only the IGHG1 isotype, had an expansion of identical sequences across multiple visits including baseline as visualized by the largest pie in **Figure 5B**. This largest node comprises of 58 individual BCR sequences wherein 34 of them are derived from d5 and 20 BCRs could not be assigned to any visit.

CSR Events within the Clonotypes

We investigated the clonotypes for the CSR events by querying clones with dif-

ferent IGHC chains. Of 369 clonotypes shared between different visits, 191 clonotypes used the same constant gene and do not represent clonotypes with CSR. Interestingly, a majority of clonotypes (53%; 101 of 191) only used the IGHG1 gene, 21% clonotypes used IGHA1 followed by 10% using IGHM and 8% using IGHG2. Thus, clonotypes followed the same trend as constant gene usage. Of 178 clonotypes that used multiple constant genes, 17% used IGHG1 and IGHA1 (**Figure 5C**). IGHG1 is clustered with IGHM three times more (74%) as compared to IGHG2 clustering with IGHM. Similarly, IGHA1 is clustered with IGHM three times more than IGHA2, suggesting high CSR between IGHM and IGHA1. Overall, we found that 45% of these clonotypes contained IGHM and IGHG isotypes, followed by IGHM and IGHA (29%). The usage of multiple constant genes in the clonotypes suggest a high IGHG1 response followed by IGHA1.

Clonal Lineages of the Clonotypes with CSR Events

We selected a few of the large clonotypes to visualize the class-switching process via lineage construction. While some of the clones (e.g., clone 660, utilizing almost exclusively IGHG1 with one IGHA1) were highly mutated and diverse (**Figure S4B**), others (e.g., clone 1980) showed a more conserved mutation pattern with very few mutations separating the clone members (**Figure 5D**). Clone 1980 is the 20th largest clone where the IGHA and IGHG constant genes expanded with identical sequence in the V genes, which were only one to four mutations away from the IGHM harboring BCR (**Figure 5D**). This is an example of a receptor wherein the BCRs at later time-points harbor fewer mutations as compared to the germline than the BCRs sampled on do. This suggests that this clone is derived from memory responses generated during previous antigen encounters.

Comparable Length of Most of the Junctions

Similarly, CDR3 length distribution was plotted for all the cells grouped by clonotype at baseline and each visit post-vaccination. We observed a larger proportion of clonotypes with CDR3 lengths of 12 amino acids at d5 (mean length of CDR3: 15.8 ± 3.8 amino acid residues) and 15 amino acids at d7 (mean length of CDR3: 15.6 ± 3.1 amino acid residues). We also observed a few clonotypes with longer junction region at d5 and d7 post-vaccination (**Figure S4C**).

Mutation Load in BCRs upon Vaccination

The selection process for higher affinity Abs during the GC response also leaves an imprint on the IGHV genes, in terms of the type of amino acid substitutions observed in the cells which have successfully passed selection. Analysis of such mutation patterns at the nucleotide level allows us to understand the adaptability of the immune system to the antigens encountered during vaccination.

Positively Correlated Mutations in Heavy and Light Chain Genes

The majority of the BCRs in the activated memory B cells used the IGHM (34 cells) gene followed by the IGHA1 (6 cells) constant genes. As expected, the mutation load between memory B cells (cluster B2) and activated memory B cells (cluster B3) was not significantly different. We observed that the IGHG1 and IGHM BCRs

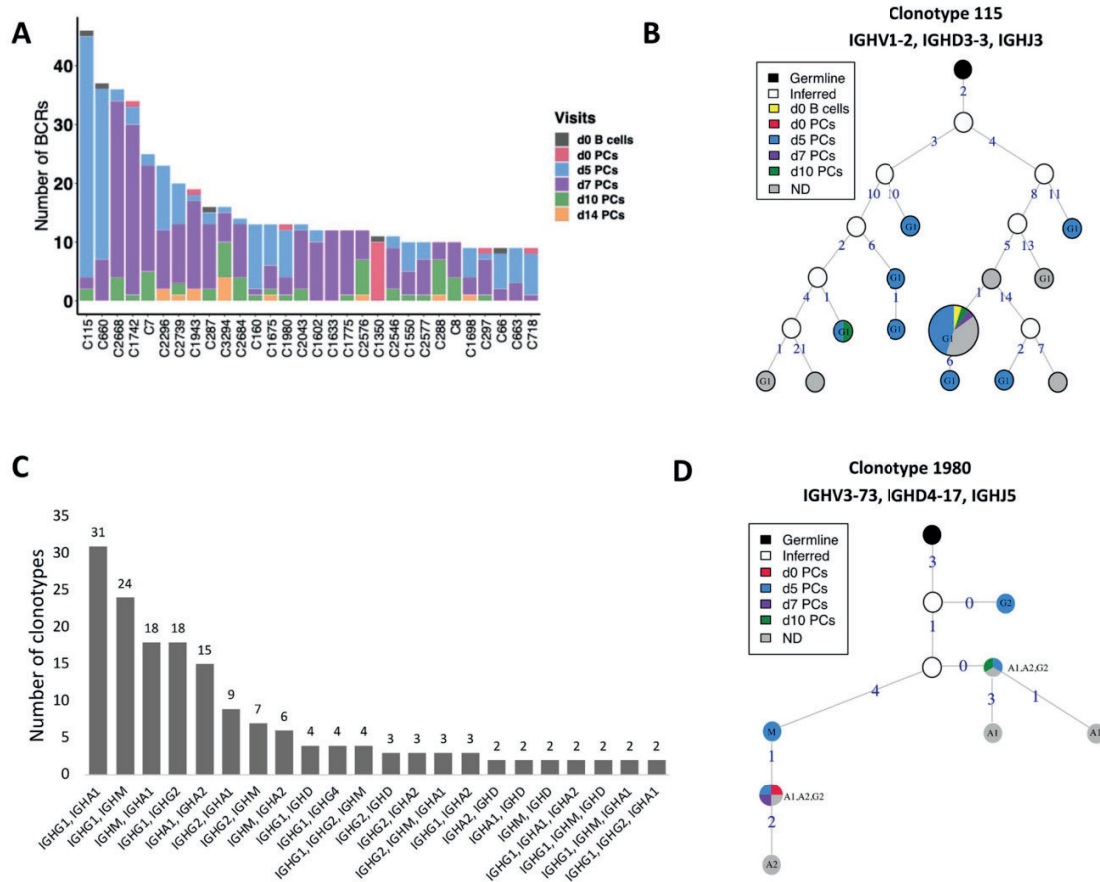

Figure 5. BCR clonotypes over different time-points. (A) 30 most numerous clonotypes over different time-points pre- and post-vaccination. Contribution of different visits to the total size of a clone is indicated by colors. (B) Clonal lineage of clonotype 115. The graph is constructed using V gene germline sequence as the root node. The size of each node is scaled and directly related to the number of BCRs for that particular sequence. The nodes are colored based on the visits from which sequences are derived. The unique sequences present across multiple visits are also grouped and colored differently as mentioned in the legend. Germline is colored black and the inferred nodes are colored white. The edge label indicates the number of different nucleotides as compared to the previous node. (C) A bar plot indicating the >2 clonotypes containing cells with multiple constant genes. For example; each of 31 clonotypes consist of sequences using IGHG1 and IGHA1 constant genes. The number of clonotypes for each combination is mentioned on the top of bar. (D) Clonal lineage of clonotype 1980 with class-switch recombination events. Additional inferred nodes were added to correctly represent the order of class-switching.

in PB/PCs had significantly more mutations ($p < 0.05$; < 0.001) in the complete V gene as compared to the memory and activated memory B cells sampled at d0 (**Figure 6A**). The mutations in V region in sequences using IGHG1 constant gene are also accounted for in the CDR1 and FR3 region whereas for IGHM the significant differences were also observed in FR2, CDR2 and FR3 regions. We observed that IGHV of BCRs utilizing IGHG1, in general, harbored more mutations in post-vaccination visits as compared to other constant genes in all V regions (**Figure 6A**), which might be associated with the expansion in the IGHG1 BCRs post-vaccination. Moreover, we found that the mutations in heavy chains were positively correlated with the mutations in the light chain in all the regions with significant p values (**Figure 6B**).

Figure 6. SHM levels in the V genes in heavy and light chains. (A) The boxplot representing the number of mutations in the V genes of BCRs over different time-points pre- and post-vaccination per different constant gene. The mutations have been identified in each cell over framework and complementarity determining regions in the V region. The cells at do are divided over naive B cells, memory B cells, activated memory B cells and PB/PCs. Each dot is a sequence from a single cell. The significant mean differences as calculated by the t-test are highlighted by asterix as *: 0.05–0.01, **: 0.01–0.001 and *** < 0.001. (B) The correlation of mutation numbers in all the V regions between heavy and light variable genes for all cells with known paired constant BCRs. The regression line is fitted and the correlation and p values are indicated on top.

Positive Selection of Mutations in the CDR Region over Time

To further confirm that the mutations in PB/PCs were antigen driven, we employed BASELINE [21] to detect the selection by analyzing mutation patterns in experimentally derived Ig sequences. We observed a negative/neutral selection in framework regions and slightly positive selection in the CDRs (**Figure S5**). The differences between the selection estimates in both FWR and CDR regions were highly significant ($p \leq 0.03$) except in FWR region at visit d10 ($p = 0.25$). The positive selection of mutations in CDRs and negative selection in FWRs correspond with normal antigen-specific B cells [22]. Moreover, we did not observe a varying trend i.e., increasing or decreasing selection pressure in CDRs over time suggesting that the selected receptors were already available at the beginning of the response and these were recruited over time for optimum immune response.

BCRs Specific to Vaccine Toxoids

To identify toxoid-specific lineages in the scBCR-rep, we searched literature for the CDR3 sequences known to be specific to antigens present in the Boostrix vaccine. We used the CDR3 amino acid sequences of the (mono-)clonal Abs for the anti-DT [23], anti-TT [24] and anti-PT [25] to query the related BCRs in our data (**Figure S6**). To account for individual-specific variability in the CDR3 sequences (as a result of SHM and affinity maturation processes specific to the individuals), we allowed a certain level of flexibility in our search. Apart from relaxing the identity of the CDR3 sequence at the amino acid level to 60–70%, the length of the CDR3 sequences was also allowed to vary by 1-3 amino acid residues.

Identification of Conserved Anti-TT BCRs

We could not identify any relevant BCR sequence highly related to the anti-DT Ab sequences previously published. However, we identified 54 BCRs from 25 clonotypes that were highly similar to anti-TT Ab query sequences. 65% of the observed anti-TT BCR clones used the IGHG1 constant gene followed by the IGHA1 (13%), IGHM (15%) and IGHA2 (6%) genes. IGHG1 was observed at all time-points, whereas IGHA1, IGHA2 and IGHM were observed only until d7 post-vaccination. Clone 288 and 291 are 82% and 88% identical to the query anti-TT Ab sequence (**Figure 7A**). Similarly, clone 681 and 2083 are 80% and 86% identical to their respective anti-TT Ab query sequences. Clone 288 was the largest expanded clone with anti-TT specific BCRs (**Figure 7B**). This clone was present mostly at the later time-points post-vaccination. The presence of highly conserved BCR clones to the queried anti-TT Ab sequences suggests the BCRs can be highly conserved among different individuals. Furthermore, it also suggests that the immune response against TT is memorized efficiently by the immune system for secondary responses.

Identification of BCRs (Un-)Likely Related to Anti-PT BCRs

Analogously, we identified 20 BCRs that were similar to the anti-PT Ab query sequences, however the BCRs were not conserved as compared to the query sequences. This might suggest that the selected BCRs may be specific to antigens other than PT. 55% of the hits used the IGHG1 gene sampled from all visits, fol-

Chapter 3.3

lowed by 30% IGHM BCRs sampled from the memory B cells (cluster B3) at baseline. Unlike the anti-TT BCR sequences, we also observed a few BCRs using the IGHD constant gene. One clone with maximum identity (~70%) to the anti-PT Ab query sequence was found (**Figure 7C**). This clone used the IGHG1 constant gene. Clone 2450 is 73% identical to its respective anti-PT Ab query sequence. We did not observe highly conserved (>80%) CDR3 sequences to the anti-PT Ab query sequences suggesting either a unique individual-specific repertoire or recurrent adaptability of the immune response to the subsequent encounter of the antigen i.e., PT.

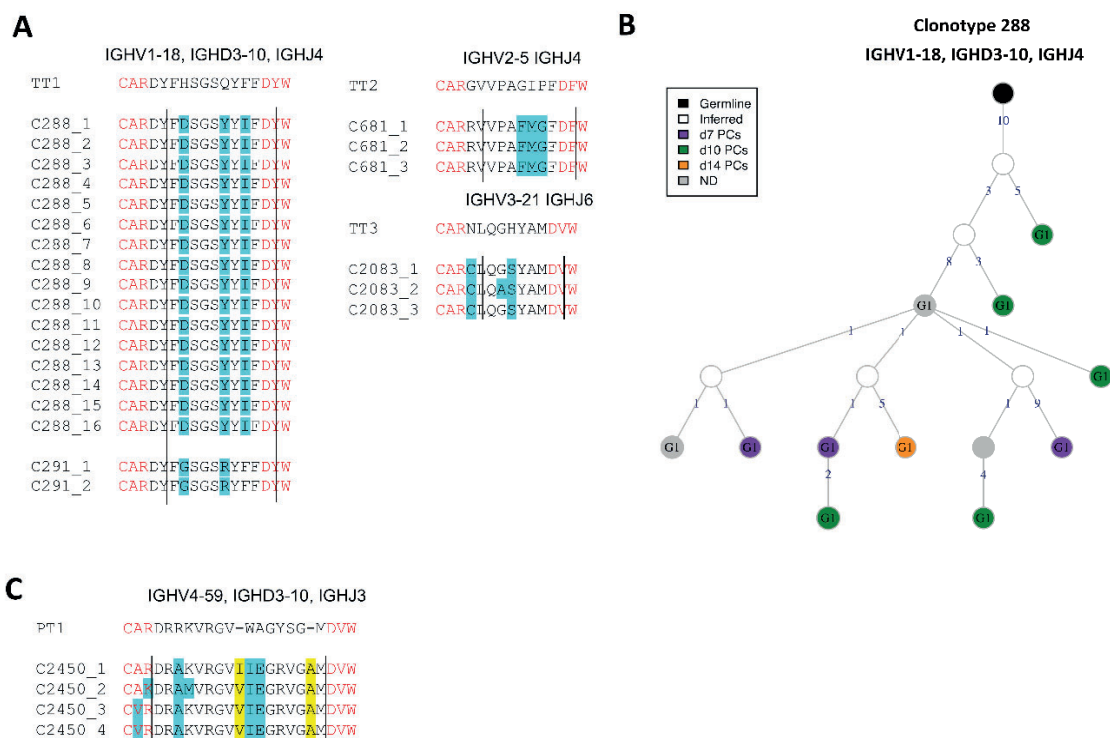

Figure 7. Toxoid-specific lineages upon Boostrix vaccination. (A) Highly conserved anti-tetanus toxoid BCR clonotypes. Four clonotypes with >80% identity are aligned to the anti-TT Ab query sequences. The changed residues are highlighted in cyan and clonotype IDs are mentioned. The V and J gene residues are highlighted in red and demarcated by straight lines. (B) BCR lineage of anti-tetanus toxoid clonotype 288. The largest anti-TT BCR clonotype is visualized. (C) (Un-)likely related anti-pertussis toxoid BCR clonotypes. One clonotype with >70% identity is aligned to the respective anti-PT Ab query sequences. The length flexibility allowed the identification of these clonotypes. The changed residues are highlighted in cyan and the insertions are highlighted in yellow. Clonotype IDs are mentioned.

Discussion

Understanding human B-cell immune responses to infections is critical for vaccine development and assessment [26]. The repertoire of antigen receptor sequences changes during an encounter with foreign antigen from pathogens/vaccination [19,27]. Identifying the signatures of effective responses from the repertoire data is challenging and systematic analysis of the repertoire together with the dynamics of clonal lineages during infection/vaccination is crucial. Here, we systematically characterized the cell types in sorted B cells and PB/PCs using sin-

gle-cell transcriptomics data and developed a robust workflow to capture the longitudinal changes (do, 5, 7, 10, and 14 after Boostrix vaccination) in the BCRs and clonal lineages using repertoire data from the same cells. Moreover, we accorded our results with previously acquired flow cytometry data from the same individual [5]. We identified additional membrane markers that could be used in flow cytometry to dissect the maturation of PB/PCs. Furthermore, using one individual, we developed a bioinformatic workflow as a proof-of-principle to compare the BCR-rep in PB/PCs with the baseline B-cell repertoire and reported expansion of unique clones in post-vaccination visits, high usage of IGHG1 in expanded clones, increased class switching events post-vaccination and positive selection of CDR3 sequences over time. We also found that the Variable gene family-based clustering of BCRs improved the clustering of BCRs. Finally, the query tool developed in the study dissect the immune response to the components of Boostrix vaccine is unique to this study. Albeit that this pilot study contains only one individual, this study still allows us to select for the right processes to be evaluated in a larger series. Additionally, the analysis performed in one individual could impact the biological findings in our study, especially, the V(D)J gene usage and clonal lineage analysis, which should be assessed in larger studies.

The classical markers used in phenotyping by flow cytometry are not always captured in the sparse single-cell transcriptomics data which makes it challenging to define uniform populations in both the technologies. Therefore, the identification of naive B cells, memory B cells, activated memory B cells and plasma cell clusters was made using a combination of classical CD markers and other gene-based markers known in the literature. For example, CXCR4, a chemokine receptor, turned out to be an important marker for the identification of the naive B cells [16], whereas the classical markers IGHD, CD19 were dimly expressed in this cell subset. Also, CXCR4 is known to be progressively downregulated in transition from naive B cells to memory B cells to activated memory B cells [19], which we also observed in clusters B1, B2 and B3 (Figure 1D). The activated memory B-cell state displays a hallmark of an effector B-cell response and shares several markers with previously defined aged/autoimmunity-associated B cells, e.g., high expression of ITGAX (CD11c) [28]. Another activated memory B-cell marker, i.e., ZBTB32, is known to modulate the duration of memory B-cell recall responses in mice [29]. Defining the B-cell populations accurately helps in better understanding of the molecular processes e.g., immunoglobulin production, antigen processing and presentation and glycolysation in vaccination/infection (Figure 2F), which in turn might be helpful in identifying therapeutic targets in pathogen immunity. Moreover, among all activated memory B-cell markers, ITGAX, CD72 and TNFRSF1B are membrane markers, that in addition to the classical B-cell markers can be used to sort activated memory B cells.

Despite regressing out cell cycle genes, we still observed a high score for the G2+S genes in the P4 cluster, suggestive of the most proliferating PB/PCs. Although we did not consider the cell cycle genes for lineage tracing, the P4 plasma cell cluster was the endpoint of the trajectory, which suggests the role of developmental ge-

nes other than cell cycle genes in the plasma cell development and proliferation. Interestingly, these P1-P4 clusters of PB/PCs do not accurately depict the developmental stages of PB/PCs as defined by the CD20 and CD138 markers in flow cytometry [5]. We showed that using flow cytometry data as a reference, the stages of plasma cell maturation could be tracked accurately and additional plasma cell maturation markers, contributing from the early to late plasma cell maturation pathway, were identified. For example, peroxiredoxin PRDX3 (similar expression as SELL (CD62L)) suffices the metabolic requirements of PCs in early phase of development that are destined to secrete massive amounts of Ig [30]. PPIA, peptidyl-prolyl isomerase A, catalyzes the protein folding and might play an important role in folding the Abs in the early phase of plasma cell development. Additionally, PABPC1 (expression similar to CD19) mediates the regulation of the switching from membrane IgH to secreted IgH isoform in PCs [31]. CD74 (expression similar to MS4A1 (CD20)) is directly involved in shaping the scB-CR-rep by initiating a cascade that results in proliferation of B cells and rescues the cells from apoptosis [32,33]. MZB1 (expression similar to CD27) is an important co-chaperone in plasma cell differentiation [34]. Loss of this gene can affect migratory properties of the Ab secreting cells and their trafficking and retention to the bone marrow [34]. Similarly, the SSR4 gene plays an important role in protein assembly and trafficking [35]. Its high expression is related to IgG4-related diseases [36]. The markers DDOST and PPIB (expression similar to CD38) are involved in protein glycosylation and unfolded protein responses in the plasma cell development process as also identified in the pathway analysis. Finally, XBP1 (similar expression as SDC1 (CD138)) is responsible for late events i.e., increased protein synthesis in plasma cell differentiation [37,38]. Herein, 32% of 104 genes were found to express membrane bound proteins and hence can be used in flow cytometry to dissect additional stages of plasma cell maturation and/or sort specific populations e.g., Ab-secreting cells. A few of these markers e.g., CD74 [39] and CD22 [40] have already been used in quantitative flow cytometry studies to distinguish normal B cells from the B-cell related malignancies.

The repertoire in response to infection/vaccination has generally preference for specific V, D or J genes. For example, anti-hemagglutinin clones have been shown to use the IGHV1-69 gene [35,41] and IGHV4-34 gene [19] is abundant in influenza vaccination/infection studies. However, the usage of the IGHV3-7 gene increased after Hepatitis B vaccination [42]. Also, the abundance of the IGHV4-59, IGHV4-39, IGHV3-23, IGHV3-53, IGH3-66, IGHV2-5, and IGHV2-70 genes was found in SARS-CoV2 infection studies [43,44,45,46]. Similarly, we observed an increased usage of the IGHV3-23 gene on all visits post-vaccination; the usage of the IGHV1-2, IGHV1-18, IGHV3-33, IGHV4-39, IGHV4-31 genes increased at d5, d7 and d10 post-vaccination; and IGHV5-51 was highly used at d10 post-vaccination. We found that none of the specific classes of the IGHV genes has driven the overall response. Moreover, we identified high usage of the IGHD3 family and the IGHJ6 gene, which is in general abundantly used in the general repertoire [47,48,49], most likely owing to the perfect recombination signal sequences [50,51]. In the light chains, we also observed a high usage of the IGK genes as

compared to the IGL loci gene, reflecting the normal 3:2 ratio observed in humans at baseline [52,53,54], which was skewed to a ~8:3 ratio at d5, suggesting selection mechanisms due to the antigen exposure.

We identified ~900 of ~3500 clonotypes with >1 BCR clustered together. The majority of them were present on d5 and d7 post-vaccination. Although, the PB/PCs expanded after vaccination are enriched for vaccine-specificity, we cannot rule out that some of the PCs may have a different specificity [55,56]. Approximately, 70% of the Ab-secreting cells in the influenza vaccination study have been shown to be influenza-vaccine specific, previously [8]. The clonotype classification allowed us to identify class-switching events, the majority of which contained IGHM and IGHG, followed by IGHM and IGHA. It is known from previous studies that ~85% of the switches from IgM commonly comprises of IgG1, IgA1 and IgG2 in decreasing order [57]. Higher usage of the IgG subclasses (48% IgG1, 22% IgG2, and 9% IgG3) has been known previously from influenza vaccine responsive clones [19], which was also observed in our study. Altogether, the highest usage of the IGHG1 gene and the highest number of clonotypes containing IgM and IgG suggest the vaccine target IgG-based immune response, common immune response in intramuscular vaccine administration.

The selection processes and molecular events affect the V gene of IG heavy chain differently than the light chains [58,59] resulting in less diversity in the light chain repertoire [60]. Although we observed significant correlations between the mutations in V regions in heavy and light chain genes, the correlation was <45%. The high mutation rate in IGHV BCRs utilizing the IGHM class has been proposed as a mechanism of the immune system to maintain long-term memory to the vaccine [61]. Moreover, the high number of mutations in IGHG1 and IGHM genes in CDR and FR3 regions might also be associated with the maturation of IgG affinity during the response to the Boostrix vaccine. As the vaccine is a booster and only one individual was used for the pilot study, it might be difficult to assess the role of booster in affinity maturation processes.

The dissection of the immune response to all the antigens and/or separate components of a vaccine, when cells are not pre-sorted based on their reactivity, can be helpful to estimate the response to each of the antigens. We identified a few clonotypes related to anti-TT and anti-PT BCRs, suggesting the public nature of the queried sequences. Identification of highly conserved anti-TT BCRs suggests an optimal repertoire for strong immunodominant epitopes. However, we observed that the anti-PT BCRs were not highly conserved which could be explained by either a unique private repertoire to the antigen or that each encounter with this antigen shapes the repertoire with additional mutations. The number of identified anti-TT and anti-PT clones are not directly related to the complexity of the proteins in the vaccine but related to the number of epitopes found in the literature. Additional support to this observation can be obtained with repertoire data obtained from antigen-specific B cells from multiple individuals.

Chapter 3.3

Overall, we identified B-cell populations and additional plasma cell maturation pathway biomarkers based on the transcriptomics data. Importantly, we used the longitudinal scBCR-rep data to understand the V(D)JC gene usage, clonal expansion and SHM events post-vaccination and their role in shaping immune responses. Together, we were able to dissect the immune responses to the components of the Boostrix vaccine.

Conclusions

To conclude, we have characterized the PB/PCs response of an immunized donor by performing longitudinal analysis (d0, 5, 7, 10, and 14 after Boostrix vaccination) of the single-cell transcriptome as well as the B-cell receptor (BCR) repertoire (scBCR-rep) data and comparing them with the flow cytometry data from the same donor. We report that the conventional membrane protein markers for cell type identification in flow cytometry do not match transcript expression levels. Hence, proper B-cell subsetting based on gene expression profile requires use of additional parameters. Also, the flowcytometry data guided us to trace the maturation pathway of the PB/PCs, which was not feasible with the single-cell transcriptomic data, owing to differences in the transcript level expression. However, after tracing the maturation pathway, we could find multiple additional membrane markers e.g., CD37, CD52, CD22, CD53, FCER2 that could be used in flow cytometry to dissect the maturation of PB/PCs. Furthermore, in this study, we developed a methodology to compare the BCR-rep in PB/PCs with the baseline B-cell repertoire and reported expansion of unique clones in post-vaccination visits, high usage of IGHG1 in expanded clones, increased class-switching events post-vaccination and positive selection of CDR3 sequences over time. We also found that the Variable gene family-based clustering of BCRs improved the clustering of BCRs. Finally, the query tool developed in the study to dissect the immune response to the components of the Boostrix vaccine is unique to this study.

J. J. M. van Dongen is the founder of the EuroClonality Consortium and one of the inventors on the EuroClonality-owned patents and EuroFlow-owned patents, which are licensed to Invivoscribe, BD Biosciences or Cytognos; these companies pay royalties to the EuroClonality and EuroFlow Consortia, respectively, which are exclusively used for sustainability of these consortia. J. J. M. van Dongen reports an Educational Services Agreement with BD Biosciences and a Scientific Advisory Agreement with Cytognos, with honorarium fees paid to LUMC. The rest of the authors declare that they have no other relevant conflicts of interest.
