ABSTRACT

Context. The Rosetta and *Giotto* missions investigated the composition of the cometary comae of 67P/Churyumov-Gerasimenko and 1P/Halley, respectively. In both cases, a surprisingly large amount of molecular oxygen (O_2) was detected and was well correlated with the observed abundances of H₂O. Laboratory experiments simulating chemical processing for various astronomical environments already showed that formation of solid state O_2 is linked to water. However, a quantitative study of O_2 formation upon UV photolysis of pure H₂O and H₂O dominated interstellar ice analogues is still missing.

Aims. The goal of this work is to investigate whether the UV irradiation of H_2O -rich ice produced at the earliest stages of star formation is efficient enough to explain the observed abundance of cometary O_2 .

Methods. The photochemistry of pure $H_2^{16}O(H_2^{18}O)$ as well as mixed $H_2O:CO_2$ (ratio of 100:11, 100:22, 100:44) and $H_2O:CO_2:O_2$ (100:22:2) ices was quantified during UV photolysis. Laser desorption post-ionisation time of flight mass spectrometry (LDPI TOF MS) was used to probe molecular abundances in the ice as a function of UV fluence.

Results. Upon UV photolysis of pure amorphous H_2O ice, deposited at 20 K, formation of O_2 and H_2O_2 is observed at abundances of, respectively, $(0.9 \pm 0.2)\%$ (O_2/H_2O) and $(1.3 \pm 0.3)\%$ (H_2O_2/H_2O) . To the best of our knowledge, this is the first quantitative characterisation of the kinetics of this process. During the UV photolysis of mixed H_2O : CO_2 ices, the formation of the relative amount of O_2 compared to H_2O increases to a level of $(1.6 \pm 0.4)\%$ (for H_2O : CO_2 ratio of 100:22), while the (H_2O_2/H_2O) yield remains similar to experiments with pure water. In an ice enriched with O_2 (2%), the O_2 level increases up to 7% with regard to H_2O , at low UV fluence, which is higher than expected on the basis of the enrichment alone. The resulting O_2/H_2O values derived for the H_2O and H_2O : CO_2 ices may account for a (substantial) part of the high oxygen amounts found in the comae of 67P and 1P.

1. Introduction

A major development in observations of O_2 beyond our Earth was made in 2015 with the Rosetta space mission (Bieler et al. 2015). The composition of the cometary coma of 67P/Churyumov-Gerasimenko (67P) was measured utilising mass spectrometry. A relatively large amount of O_2 was detected with its abundance well correlated with H₂O. The average concentration of O_2/H_2O in the ice was determined as (3.1 ± 1.1)%, well above the expected gas-phase ratio in the interstellar medium (ISM) (Woodall et al. 2007; Yıldız et al. 2013). Motivated by this detection, data collected by the *Giotto* mission, which measured the composition of the cometary coma of 1P/Halley (1P), was re-analysed. As a result, an average concentration of O_2/H_2O in 1P was derived at (3.7 ± 1.7)% (Rubin et al. 2015).

Following these findings, a number of hypotheses have been proposed to explain the unexpectedly high O_2 comet abundances and its scaling with H₂O. Among different scenarios reviewed by Luspay-Kuti et al. (2018), a primordial origin of O_2 and H₂O has been put forward, which is in agreement with the common origin of these dynamically different comets (Rubin et al. 2015). In the primordial scenario, the nuclei of comets are formed via the agglomeration of icy grains that formed during the dark molecular cloud stage or from more processed grains, frozen out during the protosolar nebula stage. In other words, the composition of the comet nuclei is expected to reflect, to a certain extent, the final composition of interstellar ices at the early stages of the star formation sequence.

Water is the main component of interstellar and cometary ices (Whittet et al. 1988; Bockelée-Morvan et al. 2000; Boogert et al. 2008). Solid O_2 has not been detected because of its homo-nuclear diatomic nature, which turns the molecule nearly invisible in the infrared and millimetre-wavelength regime. As an alternative method, an infrared transition induced by O_2 interacting with a surrounding matrix, could offer a detection, but was shown to be too weak for an astronomical identification (Müller et al. 2018). Hence, only generous upper limits of the O_2/H_2O ratio in the solid are available with values of 15% and 39%, towards the low-mass protostar R CrA IRS2 and the massive protostar NGC 7538 IRS9, respectively (Vandenbussche et al. 1999). This is insufficient to test the hypothesis of a primordial origin of cometary O_2 .

Constraining observations of the gas-phase species provides a complimentary view of the involved gas-grain chemistry. In this case, however, it is important to note that the majority of water in the ISM resides in the ice, rather than in the gas. In addition, gas-phase chemistry as well as (non) thermal desorption mechanisms complicate the link between ice and gas. Despite low gas-phase abundances and challenging detection methods, a comparison of measured gas-phase abundances of H₂O with respect to O₂ has been made possible for ρ Oph A (Larsson et al. 2007; Liseau et al. 2012; Larsson & Liseau 2017). In the cold and dark regions of ρ Oph A, the derived ratio of O₂/H₂O abundances reaches 10, significantly varying from cometary measurements and further convoluting the understanding of O₂ in the ice.

A different approach to investigate the link between O₂ and H₂O in solid state is with astrochemical modelling. Taquet et al. (2016) explored a grid of physical parameters which demonstrated that under specific dark cloud conditions, the resulting solid O_2/H_2O values and abundances of related species (H_2O_2 , HO₂) could match the findings already cited here for 67P. In this model, the high O₂/H₂O value was a direct result of grain surface reactions at temperatures between 10 and 20 K and based on a formation pathway of O_2 proceeding via recombination of O atoms (Tielens & Hagen 1982; Cuppen et al. 2010). This reaction competes with the hydrogenation of O, O_2 or O_3 , which depletes most of the O and O₂ reservoir and eventually leads to efficient formation of H₂O (Ioppolo et al. 2008, 2010; Oba et al. 2009; Miyauchi et al. 2008; Lamberts et al. 2013). An alternative way of linking solid state O2 and H2O is through processing by various energetic particles - cosmic rays (CR), electrons, and UV photons. These processes play an important role in altering the solid state chemical reservoir in molecular clouds and protoplanetary discs. The energetic processing of H₂O-rich ice can result in the production of O₂, as shown in a series of laboratory studies (e.g. Johnson 1991; Baragiola et al. 2002; Kimmel & Orlando 1995; Öberg et al. 2009b). The final impact of each irradiation type depends on local parameters, including the density, ice thickness (related to penetration depth), and proximity of radiation sources.

Upon radiolysis of water ice, H₂O molecules may desorb, ionise, or dissociate, with resulting transients reacting to form other products such as O₂, O₃ and H₂O₂ (Johnson & Quickenden 1997). The observed conversion from H₂O to O₂ has been described with a simplified reaction: 2 H₂O (solid) \rightarrow 2 H₂ (gas) + O₂ (gas). The measured sputtered O₂ yields (gas-phase) can vary across 4 orders of magnitude for different particles and energies, from 5 × 10⁻⁷ to 5 × 10⁻³ molecules eV⁻¹ (e.g. Brown et al. 1982; Bar-Nun et al. 1985; see Teolis et al. 2017 for an overview).

The effects of electron bombardment of H_2O and D_2O ice have been previously studied by, for example, Sieger et al. (1998) and Zheng et al. (2006a). Based on these investigations, processing of water ice with different energy doses (0– 500 eV molecule⁻¹) was found to result in the formation of H, O, OH, H_2 , O_2 , and H_2O_2 . Relatively higher yields of stable products were observed for amorphous water ice compared to crystalline ice (Zheng et al. 2007). Moreover, it was shown that the formation efficiency decreases with increasing ice temperature (12–90 K) (Zheng et al. 2006b).

The first study of UV photolysis of water ice demonstrated its photodesorption at temperatures between 35 and 100 K (Westley et al. 1995). Subsequently, Gerakines et al. (1996) showed that UV photolysis of H₂O ice at 10 K also leads to formation of OH, H₂O₂, and HO₂. In addition, UV photolysis triggers amorphisation of the ice (Leto & Baratta 2003). In the more recent studies focusing on the UV photodesorption of H₂O, O₂ photodesorption was also detected, but it was not possible to derive its production yield in the solid state (Öberg et al. 2009b; Cruz-Diaz et al. 2018; Fillion et al. 2021). Additionally, the UVtriggered photodesorption and photochemistry of pure O_2 ice was characterised (Zhen & Linnartz 2014).

During the last few decades, the formation of O₂ upon energetic processing of H₂O ice has been strongly supported by experiments. However, the efficiency of this process and the involved chemical pathways remain under debate. As formation of O_2 in the solid state cannot be measured by regular infrared (IR) spectroscopic techniques, to date, only the previously mentioned radiolysis experiments list quantitative yields on the O_2 (gas) formation from water ice. These yields were measured with quadrupole mass spectrometry, which inherently measures an equilibrated gas-phase composition in the experimental chamber. This means that molecules, prior to being detected, may interact with the walls and other inner parts of the setup, which are typically at room temperature. This might affect the measurements as both H₂O₂ and O₃ can decompose on metal surfaces following general equations, $2H_2O_2 \rightarrow 2H_2O +$ O_2 and $2O_3 \rightarrow 3O_2$, further complicating the calculation of precise formation yields.

In this work, we revisit the UV photolysis of pure water and water-rich ice mixtures, utilising a recently developed new diagnostic method that studies UV-irradiated ices in situ and in real time combining laser desorption and mass spectrometry. This allows us to quantitatively trace ice composition, prior to the interaction of the ablated material of the ice with the walls of the setup or the ion optics of the mass spectrometer. The method offers an alternative to spectroscopic techniques to study species with no or weak dipole moments, such as O_2 , N_2 , C_2 , S_2 , etc. This paper is organised as follows: a description of the experimental methods is given in Sect. 2, the results and a follow-up discussion are presented in Sects. 3 and 4, the astrochemical implications are discussed in Sect. 5, and the concluding remarks are summarised in Sect. 6.

2. Experiments

The experiments were carried out in the ultra-high vacuum (UHV) system $MATRI^2CES - Mass$ Analysis Tool to study Reactions in Interstellar ICES. This section includes a brief description of the setup, a list of completed experiments, and the analysis routine used to quantify the acquired data. A detailed description of the system can be found in Paardekooper et al. (2014).

2.1. Experimental setup

MATRI²CES consists of a main chamber connected with a UHV gate valve to a time of flight mass spectrometer (TOF MS) tube. The base pressure in both chambers is in the $\sim 10^{-10}$ mbar range. The main chamber houses a closed-cycle helium cryostat which cools a 1.5×5 cm gold-coated copper block used as a chemically inert substrate for ice deposition. A thermocouple and a resistive heater are attached to the base of the substrate, which allows us to set its temperature in the 20-300 K range with a relative precision of 0.25 K. In addition, the cryostat (substrate) is mounted on a two-dimensional translation stage, allowing us to shift its position in the horizontal and vertical directions. Upon reaching the deposition temperature, the vapor and gas samples are admitted through a capillary positioned at 85 degrees with respect to the substrate (front deposition) or pointed away from the substrate (background deposition). Pure water (H₂O, milliQ or H₂¹⁸O, Sigma-Aldrich, 97%¹⁸O) and

mixtures with carbon dioxide (CO₂, 99.99% purity) and molecular oxygen (O₂, 99.99% purity) are used. Prior to the deposition, liquid samples are purified from the dissolved air contamination by performing three freeze-pump-thaw cycles. A continuous deposition is regulated by a high precision needle valve, which allows the gas-phase sample to go into the main chamber. The growth rate of the ice is determined in advance using He-Ne laser (wavelength 632.8 nm) interference measurements (Baratta & Palumbo 1998; Bulak et al. 2020). To calculate the deposition rate for H₂O (background deposition) and CO₂ (front deposition), the refractive indices (1.2, and 1.21) and densities $(0.94 \text{ g cm}^{-3}, 0.98 \text{ g cm}^{-3})$, respectively, are taken from the literature (Kofman et al. 2019; Satorre et al. 2008; Jenniskens et al. 1998). In case of the deposition of $H_2O:CO_2:O_2$, the mixture was premixed at the intended ratio and deposited through the front deposition capillary following a growth rate calibration for H₂O and CO₂. In all experiments, the deposited ice column density is close to 9×10^{17} molecules cm⁻² or 90 monolayers (1 monolayer = 10^{15} molecules cm⁻²) and its uniformity across the substrate is within \pm 10%. This thickness was chosen to maximise the efficiency of photochemistry in the bulk of the ice. At the same time, a large ice thickness minimises the possible chemical reactions triggered by photoelectrons released from metal substrates upon photolysis. These effects have been restricted to the lower few MLs of the ice (e.g. Jo & White 1991; Smith et al. 2012) or not observed at all (Chuang et al. 2018).

To simulate the UV field present in the interstellar medium, a microwave discharge hydrogen lamp (MDHL) is used. It is attached to the main chamber via a (MgF₂) UHV view port directly facing the substrate. The operating conditions of the lamp (H₂ pressure of 1.44 mbar and 80 W of applied microwave power at 2.45 GHz) determine its photon flux and the spectral energy distribution (Ligterink et al. 2015). The corresponding emission spectrum consists of a Lyman- α (121.6 nm) and molecular H₂ emission bands (130–165 nm). The complete spectral energy distribution of the lamp is given in Fig. 4 in Paardekooper et al. (2016). The photon flux was measured with a NIST-calibrated silicone photodiode at the location of the substrate, 14 cm away from the lamp. The UV photon flux, after the subtraction of the optical emission, amounts to $(2.5 \pm 0.5) \times 10^{14}$ photons cm⁻² s⁻¹.

MATRI²CES uses a unique analytical approach to monitor the ice composition before, during, and after UV irradiation by combining laser desorption and mass spectrometry. This method is known as LDPI TOF MS, laser desorption post-ionisation time of flight mass spectrometry. The probing scheme is initiated by an unfocused laser beam of a Nd:YAG Polaris II (4-5 ns pulse, wavelength of 355 nm) which is guided into the main chamber at a 30-degree incidence angle with respect to the substrate (laser shot). Prior to entering the main chamber, the laser beam is trimmed to 1 mm in diameter which allows us to spatially constrain its impact on the ice. An average pulse energy (65 mJ cm⁻²) is optimised for 90 ML of water ice, as the minimum energy that probes the deposited thickness of the ice. The impact of the laser pulse on the ice triggers a local thermal desorption, creating a plume of species. The composition of the plume represents the composition of the ice at the location of the laser shot (Paardekooper et al. 2014). The plume is ionised via a continuous electron impact ionisation source (mean electron energy of 70 eV), and after an optimised time delay, a part of it is extracted into the TOF MS chamber using ion optics (plume extraction). In addition to the ionisation event, an electron impact induces the dissociation of species in the plume, which results in a molecule-specific fragmentation pattern (see Sect. 2.2). In

the field-free TOF tube, ions with different mass-to-charge ratios (m/z) are spatially separated and redirected (TOF MS in reflectron mode) into a micro-channel plate detector (MCP). This allows us to record the characteristic flight times for all m/z in the plume. This approach has several advantages: TOF MS is a very sensitive detection method, ices are investigated in situ, and signals are recorded in real time. The use of isotopologues offers a further diagnostic tool to identify newly formed species.

To increase the signal-to-noise ratio of the data, the LDPI TOF MS scheme (laser shot, plume extraction, data acquisition) is repeated at a frequency of 5 Hz, simultaneously with the automated translation of the substrate in the vertical direction. This allows us to collect 100 TOF spectra, each corresponding to a non-overlapping spot on the substrate (a column). An average of the TOF spectra in a column is mass calibrated and used to derive the composition of the ice. This scheme is repeated at an updated horizontal position (column) of the substrate, which allows us to probe the same ice while increasing the total UV photon fluence.

The acquisition of multiple data points during an irradiation experiment makes it possible to track the formation and destruction kinetics for the involved species within a single experimental run. This provides an advantage over the regular QMS TPD techniques.

2.2. Data analysis procedure

Analysis of the averaged TOF data comprises of three steps: mass calibration, integration of the mass peaks, and a conversion of the signal to an abundance (column density) of a molecule in the ice. Mass calibration of the averaged TOF spectra yields a mass resolution of $\Delta m/m \sim 250$, clearly separating each m/z. To calculate the intensity of the peaks, a Pearson IV distribution function is fitted to each feature individually. This function provides an accurate fit to the experimental data as it can account for possible asymmetry within the peak. The errors related to the integration are based on the root mean square (rms) over the residual within one standard deviation from the centre of the peak and are below the uncertainty of the ice thickness determination (±10%) (Castellanos et al. 2018).

The calculated mass peak intensities are proportional to a linear combination of species present in the plume (Paardekooper et al. 2014). This allows us to express an integrated mass spectrum, M_t , at a given irradiation time, t, by

$$M_{t} = \sum_{i=1}^{n} a_{i} \cdot \sigma_{i} \cdot M_{i}, \tag{1}$$

where a_i is the molecular abundance of species *i*, σ_i is the electron impact ionisation cross-section (at 70 eV), and M_i is the corresponding fragmentation fraction. The following crosssections are used: 2.275 (H₂O), 2.441 (O₂), 2.516 (CO), 3.521 (CO_2) Å² (Kim et al. 2014). As there is no available data in the literature for the ionisation cross-section of H₂O₂, its value is derived empirically. It is based on a linear correlation between the electron impact ionisation cross-section and polarisability (α), represented by a formula $\sigma = 1.48 \times \alpha$ (Lampe et al. 1957; Bull et al. 2012). The polarisability of H_2O_2 is 1.73 Å³ (Johnson 2020), and the derived electron impact ionisation cross-section value for H_2O_2 is 2.5 Å². The fragmentation pattern of H_2O_2 is adapted from Foner & Hudson (1962), where the contribution of fragments (peaks other than molecular ion) towards the total yield is 26%. The fragmentation patterns of other molecules relevant for this study are available in the NIST spectral database or previous works, but it should be noted that these are (slightly) dependent on the geometry of the experimental system (Kim et al. 2014). The use of these values allows us to solve Eq. (1) for a_i (arbitrary units), which is proportional to the column density of each species (mol cm⁻²), *i*.

In the final step of the analysis, the calculated water abundance (in arbitrary units) is set equal to the known thickness of the deposited ice $(9 \times 10^{16} \text{ mol cm}^{-2} \text{ or } 90 \text{ ML}$ assuming 1×10^{15} molecules per ML). Subsequently, the signals assigned to other species are converted with respect to the initial column density of water, allowing us to quantify their abundances for different UV fluences. The most significant uncertainty in this conversion is related to the uniformity of the ice thickness (±10%), and this value is taken into account when deriving abundances of photoproducts.

To translate the experimental results to environments with different astrochemical conditions, it is useful to describe the efficiency of the photoproduct formation as a molecular yield per amount of energy deposited in the ice. Hence, to calculate the fraction of absorbed photons (I_{abs}), the Beer-Lambert absorption law is used:

$$I_{abs} = I_{inc}(1 - e^{-\sigma(\lambda)_{abs}N}), \qquad (2)$$

where I_{inc} is the incident UV photon fluence, σ_{abs} is the average photon absorption cross-section of the ice (H₂O: $3.4 \times 10^{-18} \text{ cm}^{-2}$), and N is the ice column density (pure H₂O experiments: $9 \times 10^{16} \text{ mol cm}^{-2}$) (Cruz-Diaz et al. 2014a). For calculations related to mixed ices, we used the following absorption cross-section values for CO₂ and O₂: $6.7 \times 10^{-19} \text{ cm}^{-2}$ and $4.8 \times 10^{-18} \text{ cm}^{-2}$ (Cruz-Diaz et al. 2014b). For instance, after a UV irradiation of pure H₂O ice with 4.8×10^{17} photons cm⁻² (64 min), 1.3×10^{17} photons cm⁻² are absorbed: each carry, on average, 9 eV of energy (Ligterink et al. 2015). Thus, after 64 min, a total energy of 1.2×10^{18} eV is deposited in the ice and each water molecule statistically absorbs 1.3 UV photons.

2.3. Overview of experiments

In this study, we focus on different ices starting with pure H_2O , the primary constituent of interstellar ices. In a realistic interstellar ice, H₂O molecules are expected to be mixed with CO₂ (Öberg et al. 2007; Pontoppidan et al. 2008). Based on observations, the ratio of CO_2/H_2O in interstellar ices can vary from 12 to 40% (Boogert et al. 2015). Only in particular environments (Poteet et al. 2013; Isokoski et al. 2013) have pure CO₂ ices been observed. Consequently, we also investigate the photochemistry of three different H₂O:CO₂ ice mixtures. Finally, as O₂ may be formed as a side product of (non-energetic) water formation (see e.g. Cuppen et al. 2010; Minissale et al. 2014; Taquet et al. 2016), we also investigated H₂O:CO₂ ices enriched with O₂. Once O₂ is formed in an ice, it may start contributing to its overall chemical network. However, as the amount of molecular oxygen in the prestellar phase is not known, the recorded data for the O₂containing ice are presented in the appendix. Table 1 summarises all performed experiments for pure H2O ice, H2O:CO2 ice mixtures (100:11, 100:22 and 100:44), and H₂O:CO₂:O₂ (100:22:2). The assignment of the main photoproducts follows the $H_2^{16}O$ experiments, and the validity of these results is confirmed using H₂¹⁸O.

In addition to the $H_2^{18}O$ labeled experiments, another control experiment is performed to exclude error-prone results due to H_2O background contamination. In this experiment, the substrate was exposed to H_2O vapours above the sublimation point (190 K), which allows for the characterisation of the water deposited on the walls or ion optics.

Table 1. Summary of the types of performed UV photolysisexperiments.

Molecular	Composition	Temperature	UV photon fluence
composition	(%)	(K)	$(10^{18} \text{ photons cm}^{-2})$
$H_2^{16}O$	100	20	0–1.8
$H_2^{18}O$	100	20	0-1.8
H ₂ ¹⁶ O:CO ₂	100:11	20	0-1.8
H ₂ ¹⁶ O:CO ₂	100:22	20	0-2.9
H216O:CO2	100:44	20	0-2.9
$H_2^{16}O:CO_2:O_2$	100:22:2	20	0-2.9
control (H ₂ O)	100	20, 190	0-1.2

Notes. The total thickness used in all ices is 9×10^{16} mol cm⁻², which accounts for about 90 ML.

The total and incremental UV fluence with which our ice samples are irradiated are representative of the different regions in the ISM. In the centre of a dark cloud, the photon fluence is estimated to be $(3-30) \times 10^{17}$ photons cm⁻², considering cosmic ray induced secondary UV flux of $(1-10) \times 10^3$ photons cm⁻² s⁻¹ and an average molecular cloud lifetime of up to 10^7 yr (Shen et al. 2004; Chevance et al. 2020). The UV fluence during a lifetime of a protoplanetary disc was modelled by Drozdovskaya et al. (2014), and, depending on the location within the disc, it varies between 10^{16} and 10^{26} photons cm⁻².

3. Results

3.1. UV photolysis of H₂O ice

The mass spectra obtained during the UV photolysis of pure $H_2^{16}O$ and $H_2^{18}O$ ices are shown in the upper and lower panels of Fig. 1, respectively. The bottom trace in each panel (black) is a reference mass spectrum that allows us to track changes from the initial composition of the ice. For $H_2^{16}O$, the unprocessed signature includes peaks at m/z = 16, 17, 18, and 19. Peaks at $m/z = 18 \times n + 1$, where n = 1, 2, and 3 represent protonated water clusters formed in the ablated plume, that is, these are not a reaction product from the UV irradiation, but result from the laser desorption pulse (Gudipati & Yang 2012).

After UV irradiation of the ice with a fluence of 6×10^{16} photons cm⁻² (red trace, Fig. 1), new peaks appear at m/z=32, 34 in the H₂¹⁶O experiment (upper panel) and corresponding features at m/z=36 and 38 in the H₂¹⁸O experiment (lower panel). The mass shift of 4 atomic mass units (amu) reveals that the newly formed peaks represent species with two oxygen atoms. Considering the initial composition of the ice (pure H₂¹⁶O and H₂¹⁸O) and the reference mass spectra of possible photoproducts, the only species explaining these observations are O₂ and H₂O₂. In addition, the mass peak at m/z= 2 (for both isotopes) is increased, which must be due to the formation of molecular hydrogen (H₂) in the ice.

The mass spectra clearly show that upon UV irradiation of water ice, O_2 is formed in the solid state. The formation of H_2 (m/z = 2) and H_2O_2 (m/z = 33, 34 in upper panel and m/z = 37, 38 in lower panel) is observed simultaneously and it is important to note that the contribution of H_2O_2 towards mass peaks of O_2 due to electron impact ionisation is negligible (Foner & Hudson 1962). As we probe the molecular plume before its interaction with the metal walls of the setup or its ion optics, the intensity of features representing O_2^+ and $H_2O_2^+$ provides a firm base to quantify the formation of both photoproducts. This is shown as

Fig. 1. LDPI TOF MS signals for a UV-irradiated $H_2^{16}O$ (*upper panel*) and $H_2^{18}O$ (*lower panel*) ice at 20 K for increasing photon fluence. The lowest trace in each plot shows the signal without UV irradiation. Besides H_2O and its fragmentation pattern, these spectra reveal the presence of the photolysis products, H_2 , O_2 and H_2O_2 . In addition, protonated cluster ions $(H_2O)_nH^+$ are seen to form in the desorption process (see text for details).

Fig. 2. Molecular abundances of species during the UV photolysis of $H_2^{16}O$ and $H_2^{18}O$ ices at 20 K as function of photon fluence: ${}^{16}O_2$, ${}^{18}O_2$ (*upper panel*) and $H_2^{16}O_2$, $H_2^{18}O_2$ (*lower panel*). The results from four separate experiments are shown. The initial ice thickness is (90 ± 10) ML.

a function of UV fluence in Fig. 2. The abundances are calculated for multiple experiments with both isotopologues following the method described in Sect. 2.2. Subsequently, an exponential function was used to average the photoproduct yields from repeated experiments (for both isotopologues). The formation of O_2 reaches its maximum of $(7.6 \pm 2.0) \times 10^{14}$ molecules cm⁻² at an incident photon fluence of 8.9×10^{17} photons cm⁻². For the O_2 formation relative to the current H₂O abundance, we derive a maximum abundance of O_2/H_2O to be $(0.9 \pm 0.2)\%$. The formation of closely related H₂O₂ is saturated at $(1.1 \pm 0.3) \times 10^{15}$ molecules cm⁻², which is converted to a relative maximum abundance of H₂O₂/H₂O equal to $(1.3 \pm 0.3)\%$ (see Appendix A for the water consumption during the experiments in this study).

The observed kinetic curves for O_2 and H_2O_2 show the formation of both products in the early stages of photolysis. The photoproduct abundances reach a saturation level at a fluence of $(4.8-8.9) \times 10^{17}$ photons cm⁻², the exposure dose that marks the equilibrium between formation and destruction routes.

To calculate the product formation efficiency per energy dose deposited in the ice, for each step of the photolysis, only the absorbed photons are considered. For each of the presented UV irradiation doses, the corresponding fraction of incident photons absorbed by the water ice is calculated using Eq. (2) as $(26.0 \pm 6.5)\%$. The largest uncertainty in the fraction of absorbed photons is based on the error bars related to the UV photon flux (25%). By calculating the yield for each UV dose, an upper limit was determined for the O₂ formation in pure H₂O ice as $(1.3 \pm 0.3) \times 10^{-3}$ mol eV⁻¹. A similar calculation was done for H₂O₂, which results in a maximum formation yield of $(3.7 \pm 0.9) \times 10^{-3}$ mol eV⁻¹.

Fig. 3. LDPI TOF MS signals for a UV-irradiated $H_2O:CO_2$ ice at 100:11 ratio. The lowest trace in each panel shows the signal without UV irradiation. Peaks at m/z = 18n + 1, where n = 1, 2 represent protonated water clusters formed upon laser desorption of water ice and do not contribute to the chemistry in the ice. The inset is a zoom on the intensity scale for the higher masses.

3.2. UV photolysis of H₂O:CO₂ (100:11, 100:22, and 100:44)

The mass spectra obtained during the UV photolysis of the $H_2O:CO_2 = 100:11$ ice mixture are shown in Fig. 3. The mass spectra for the 100:22 and 100:44 mixtures are presented in Appendix B.

The reference mass spectrum (Fig. 3, black trace), in addition to the previously described water signatures (see Fig. 2), includes the m/z values characteristic for CO₂, that is, m/z = 12, 16, 28 and 44. Upon reaching a UV fluence of 6.0×10^{16} photons cm⁻² (red trace), a number of new m/z signals is observed. These signals are representative of the formation of H₂O₂ (m/z = 34), H₂ (m/z = 2) and CO (m/z = 28). The formation of O₂, at m/z = 32, is detected simultaneously with H₂CO (m/z = 29, 30) and HCOOH (m/z = 45 and 46). These assignments are based on the available chemical inventory in the ice and available reference mass spectra. The photoproduct formation is consistent with a decrease in the abundances of precursor species as discussed earlier (see Appendix A).

The mass spectra obtained during the photolysis of $H_2O:CO_2$ (100:22 and 100:44) ices exhibit the formation of the same photoproducts, but at different relative intensities. This change is correlated with the relative increase in the abundance of CO_2 which shifts the elemental balance towards carbon-containing species (CO, Appendix A), and also enhances the total oxygen content.

The abundances of the identified photoproducts are derived for the three mixtures following the method described in Sect. 2.2. The formed product abundances for all mixtures are shown as a function of UV fluence in Fig. 4. The maximum formation yield of O_2 reaches $(2.4 \pm 0.6) \times$ 10^{14} molecules cm⁻² (for the H₂O:CO₂ = 100:11 mixture), (3.4 ± 0.8) × 10¹⁴ molecules cm⁻² (100:22), and (5.1 ± 1.2) × 10¹⁴ molecules cm⁻² (100:44). The formation of H₂O₂ peaks at (8.5 ± 2.1) × 10¹⁴ (100:11), (3.8 ± 1.0) × 10¹⁴ molecules cm⁻² (100:22), and (4.2 ± 1.0) × 10¹⁴ molecules cm⁻² (100:44). It can be clearly seen that upon an increase in the abundance of CO₂ in the mixtures with H₂O, the maximum abundance of formed O₂ increases with the amount of CO₂ in the ice. An opposite behaviour is seen for H₂O₂ formation. Its upper limit abundance decreases, or stays constant, as the initial amount of CO₂ in the ice mixture is increased.

In all mixtures, it is found that H₂O depletes more efficiently, compared to pure H₂O ice. The formation yields of the observed species are normalised to the current amount of H₂O for each of the applied UV irradiation doses. Hence, even though the absolute yields of O₂ and H₂O₂ in mixtures are slightly lower than in pure H₂O ice photolysis, the relative abundance with respect to H₂O is increased. For the 100:11 mixture, the relative abundance of O₂/H₂O and H₂O₂/H₂O reaches, respectively, $(1.1 \pm 0.3)\%$ and $(1.2 \pm 0.3)\%$. For the 100:22 mixture, a relative abundance of O₂/H₂O and H₂O₂/H₂O reaches, respectively, $(1.6 \pm 0.4)\%$ and $(1.8 \pm 0.4)\%$. In the 100:44 mixture, relative maximum abundances of O₂/H₂O and H₂O₂/H₂O are, respectively, $(1.2 \pm 0.3)\%$ and $(1.1 \pm 0.3)\%$.

To compare the efficiency of photoproduct formation in the $H_2O:CO_2$ mixtures with the results obtained for the pure H_2O ice, the peak abundances of products at corresponding UV fluences, have been converted to formation yields per energy dose deposited in the ice. To calculate the fraction of incident photons absorbed by the $H_2O:CO_2$ ice, we considered the ratio between ice constituents and their respective UV-absorption

Fig. 4. Absolute molecular abundances of species during the UV photolysis of mixed ices: $H_2O:CO_2$ ice at 100:11 ratio (*left panel*), 100:22 (*center panel*), and 100:44 (*right panel*). Initial ice thickness is (90 ± 10) ML.

cross-sections. Consequently, for the H₂O:CO₂ (100:11, 100:22, 100:44) ice mixtures, the fraction of absorbed photons comprise $(24.5 \pm 6.1)\%$, $(22.5 \pm 5.6)\%$ and $(20.8 \pm 5.2)\%$, respectively. Here, the uncertainty in the absorbed photons is again related to the UV flux throughout the photolysis. This results in the maximum formation yields of O₂ equal to $(6.1 \pm 1.8) \times 10^{-4} \text{ mol eV}^{-1}$ (100:11), $(9.7 \pm 2.5) \times 10^{-4} \text{ mol eV}^{-1}$ (100:22), and $(6.7 \pm 2.1) \times 10^{-4} \text{ mol eV}^{-1}$ (100:44). The same calculation for H₂O₂ yields $(3.2 \pm 0.7) \times 10^{-3} \text{ mol eV}^{-1}$ (100:11), $(1.5 \pm 0.4) \times 10^{-3} \text{ mol eV}^{-1}$ (100:22), and $(3.5 \pm 1.0) \times 10^{-3} \text{ mol eV}^{-1}$ (100:44), respectively.

In addition to the mixtures studied above, where O_2 is a product of photolysis of $H_2O:CO_2$, we investigated the photoevolution of an ice, which already includes O_2 in the initial composition. The initial amount of O_2 , at a 2% level, is based on the results of modelling studies by Taquet et al. (2016). The quantitative analysis is presented in Appendix C.

4. Discussion

The results presented in the previous section allow us to discuss (i) the kinetic curves for O_2 and H_2O_2 during UV irradiation of pure H_2O ice at 20 K, (ii) the impact of including CO_2 in the initial ice composition on (absolute and relative) photoproduct formation yields, and (iii) the presence of O_2 in the initial mixture and the evolution of its abundance (and H_2O_2) as a function of UV fluence.

The formation of O_2 , H_2O_2 in pure H_2O ice is observed immediately upon the onset of UV photolysis. Its efficiency is low, at a level of X/H₂O \approx 1%. To discuss the possible formation pathways, it is useful to recall the main photodissociation channels of H₂O (Stief et al. 1975; Harich et al. 2000, 2001; van Harrevelt & van Hemert 2008; Slanger & Black 1982):

$$H_2O + h\nu \to H + OH(X^2\Pi), \tag{3}$$

 $H_2O + h\nu \to H + OH(A^2\Sigma^+), \tag{4}$

$$H_2O + h\nu \to H_2 + O(^1D), \tag{5}$$

$$H_2O + h\nu \to O(^{3}P) + H + H.$$
(6)

The potential of the newly formed free radicals as precursors for stable molecules is dictated by their abundance, relaxation rates, location within the ice, and diffusion abilities. The abundance of each fragment is given by the wavelength-dependent branching ratios following photodissociation. For H_2O in the gas-phase, relative quantum yields following UV photodissociation within the used wavelength range consistently point to OH (in its ground or first excited state) and H as a dominant channel. This, however, can be different for the solid state (see Öberg et al. 2009a and Lucas et al. 2015 for CH₃OH). It is also expected that the total effective photodissociation yield of radicals in the ice will be lower due to the recombination of fragments into the parent species. A detailed investigation of this process is required, but previous experimental studies show that the radical recombination in the water ice can decrease the photodissociation yield by 43–72%, compared to the gas phase (Mason et al. 2006; Cruz-Diaz et al. 2014a; Kalvāns 2018).

The location of the photodissociation event within the ice is important; combined with the temperature of the ice, it determines the diffusion abilities of the fragments (Andersson et al. 2006; Andersson & van Dishoeck 2008; Arasa et al. 2010). In particular, if H and OH are formed from photodissociation in the top layers of the ice (\sim 3 ML), both radicals can travel up to a few tens of angstroms within (or on top of) the ice (Andersson & van Dishoeck 2008). However, the average distance travelled by H and OH fragments in the ice is 8 Å and 1 Å, respectively. In a realistic scenario, free radicals are formed randomly throughout the ice and can be formed in two different chemical environments: at the ice and vacuum interface on the surface (including pores) and within the ice bulk. In our experiments, the ice thickness (90 ML) was chosen to maximise the contribution of the radicals created in the ice bulk; however, the exact ratio of radicals created in the bulk versus the surface (and pores) is not known. The presence of such a large parameter space significantly complicates the interpretation of our data. Nevertheless, some important observations can be made.

Under the assumption that photodissociation of H₂O mainly leads to the formation of H and OH (in the ground or excited states), the formation of H₂O₂ and H₂ can be easily accounted for by radical recombination reactions of OH+OH and H+H. However, as formation of O2 can be observed already during the early stages of irradiation, simultaneously with the formation of H_2O_2 (see Fig. 2), the involved O_2 formation routes must be connected to those of H2O2 and H2 and involve the direct products of H₂O photodissociation. Hence, we suggest that O radicals are present in the ice directly upon water photo dissociation (reactions 5 and 6). The formation of $O(^{1}D)$ via reaction (5) was demonstrated experimentally as a primary process upon photolysis of ASW (UV photolysis with 157 nm at 90 K) by Hama et al. (2009a). This radical can either proceed to react with water via $O(^{1}D)+H_{2}O \rightarrow 2OH$ (Sayós et al. 2001), or relax to its ground state and react with OH to form O2 via $O(^{3}P) + OH \rightarrow O_{2} + H$ (Hama et al. 2010). Channel (6) has not been observed experimentally; however, its contribution is not excluded as the Ly-alpha photons in our spectrum are capable of dissociating water into O(³P) (van Harrevelt & van Hemert 2008). During later stages of photolysis, secondary reaction channels, such as photodissociation of OH or recombination of

OH radicals can contribute towards the formation of $O(^{3}P)$, and consequently, O_{2} (Hama et al. 2009b, 2010).

It is also important to mention that the photodepletion of water is below ~10%. Such inefficient depletion, even for a relatively large number of absorbed photons per H₂O molecule (i.e. 4–5; see Sect. 3.1), suggests that pure water ice is resilient to UV irradiation, in part due to efficient conversion of the formed products back into H₂O.

The photolysis of $H_2O:CO_2$ ice mixtures provides additional radical precursors via the following pathways (Slanger & Black 1978; Kinugawa et al. 2011):

$$CO_2 + h\nu \to O(^{3}P) + CO(X^{1}\Sigma^{+}),$$
(7)

$$\operatorname{CO}_2 + h\nu \to \operatorname{O}(^1\mathrm{D}) + \operatorname{CO}(X^1\Sigma^+).$$
(8)

The addition of CO_2 in the ice results in a decreased absolute formation yield of O_2 and H_2O_2 in comparison to pure H_2O ice photolysis (see Figs. 2 and 4). This could be due to the lower initial abundance of water (90 ML) and/or CO_2 photodissociation products providing reactive radicals leading to competing photoproducts. Indeed, interactions of OH radicals with CO (produced by photodissociation of CO_2) lead to the (re)formation of CO_2 (Hama et al. 2010; Ioppolo et al. 2011). Consistently with fewer OH radicals available, we observe a reduced amount of formed H_2O_2 . In addition, if O radicals are present via water photodissociation (see point i) in the discussion), these fragments can also react with CO, to reform CO_2 , constraining the absolute formation of O_2 .

Increasing the relative CO₂ abundance (H₂O:CO₂ from 100:11 to 100:44) leads to a proportional increase in the O₂ formation. The maximum formation yield of O₂ is increased from $(2.4 \pm 0.6) \times 10^{14}$ molecules cm⁻² to $(5.1 \pm 1.2) \times 10^{14}$ molecules cm⁻² for H₂O:CO₂ mixtures with a ratio of 100:11 and 100:44, respectively (see Fig. 4). This is in line with the increased production of O atoms, via photodissociation of CO₂ in the ice and formation of O₂ following O+OH and O+O interactions. With more initial CO₂, the formation of H₂O₂ becomes less efficient, which could be simply due to fewer OH radicals available in the ice and the competitive reaction of CO + OH \rightarrow CO₂.

The absolute yields of O_2 and H_2O_2 during UV photolysis of mixed ices ($H_2O:CO_2$) are lower compared to pure H_2O ice, however, the relative abundances of O_2/H_2O increase. This is due to a more significant photoconversion of H_2O molecules to other species.

The analysis of the most complex $H_2O:CO_2:O_2$ ice mixture provides hints for more efficient formation pathways towards O_2 and H_2O_2 (see Appendix C). In this mixture, in addition to the previously described fragments, O radicals are available directly upon photodissociation of O_2 (Lambert et al. 2004):

$$O_2 + h\nu \to O(^{3}P) + O(^{3}P), \tag{9}$$

$$O_2 + h\nu \to O(^1D) + O(^3P).$$
⁽¹⁰⁾

At the early stages of photolysis, the formation efficiency of both O_2 and H_2O_2 (mol eV⁻¹) is an order of magnitude higher compared to other mixtures or pure water ice. The interpretation of such a result should be performed carefully, as here a precursor is included that in fact is the reaction product the experiment is aiming at. It is found, however, that the maximum abundance observed during the photolysis cannot be accounted for by the initial O_2 injection (Fig. C.2). The increased formation yield hints for additional chemical mechanisms from the pathways discussed above. These are most likely associated with the presence

of a highly reactive radical, $O({}^{1}D)$. The increased formation of O_{2} might indeed be partially due to $O({}^{1}D)$ radicals produced via the dissociation of O_{2} , reacting with CO_{2} , $H_{2}O$ or their photodissociation products (Wen & Thiemens 1993; Sayós et al. 2000). A significantly higher abundance (compared to other mixtures) is also observed for $H_{2}O_{2}$. This could be due to a barrierless reaction of $O({}^{1}D) + H_{2}O \rightarrow 2OH$, which provides precursor species for the typical radical recombination reaction (OH + OH) leading to $H_{2}O_{2}$ (Sayós et al. 2001). It is also found that $H_{2}O:CO_{2}:O_{2}$ ice mixture is the only ice studied here, where efficient formation of H_{2} is not observed. This suggests that H atoms are consumed via reactions with other ice constituents: CO, O, OH, or O_{2} .

5. Astrophysical implications

The majority of water in the ISM exists in the solid state and is formed via atom addition reactions on the grains in the dense molecular clouds (Lamberts et al. 2013; Linnartz et al. 2015; van Dishoeck et al. 2021). In addition to H₂O molecules produced by the hydrogenation of accreting O atoms $(O + H \rightarrow OH)$ and OH + H/H₂ \rightarrow H₂O), other simple molecules are formed during this stage that contribute to the bulk of observed H₂O-rich ices. These molecules include NH₃ and CH₄, produced by the hydrogenation of N and C atoms, respectively, as well as CO₂, produced through the interaction of accreting CO molecules with OH radicals (Fedoseev et al. 2015; Qasim et al. 2020; Hama et al. 2010; Ioppolo et al. 2011). Simultaneously, depending on the local physical environment, an O₂ ice reservoir can accumulate (Taquet et al. 2016). Towards the end of the accretion stage in a dense molecular cloud, the increase in chemical complexity of the icy mantles is driven by various types of energetic processing (e.g. cosmic rays, X-rays, UV photons). Later, the chemically enriched icy mantles become part of the material from which a young star, its surrounding planets and other celestial bodies, such as comets, are made from. In fact, the transfer of ices from dark clouds to protoplanetary discs and comets was discussed by Taquet et al. (2016), which showed that the chemical composition of the ices along the comet formation sequence is preserved.

To place our experiments in an astronomical context, Fig. 5 (left panel) shows the relative abundance of O₂/H₂O for the four studied ice compositions: pure H₂O and H₂O:CO₂ (100:11, 100:22, 100:44). In addition, the abundances detected in the cometary comae of 67P $(3.1 \pm 1.1)\%$ and 1P $(3.7 \pm 1.7)\%$ are marked. In the experiments we show that during the photolysis of pure H_2O ice, the O_2/H_2O ratio can increase up to a level $(0.9 \pm 0.2)\%$, roughly three-four times less than the detected abundances in the cometary comea. For ice mixtures more adequately representing icy mantles ($H_2O:CO_2$), the O_2/H_2O abundance increases with an increasing initial amount of CO₂, up to $(1.6 \pm 0.4)\%$ for the H₂O:CO₂ (100:22) ice. This value is within a of factor 2 in the range of the cometary abundances. It is expected that other abundant constituents of interstellar ices may also have an impact on relative formation of O₂/H₂O. As an example, the presence of CO can lead to a decrease in the number of available H atoms in the ice, as its successive hydrogenations lead to efficient formation of H₂CO and CH₃OH (Watanabe & Kouchi 2002). Subsequently, it would inhibit the recombination of water (OH + H), leaving OH radicals that could change the O₂/H₂O ratio. Dedicated astrochemical modelling is needed to understand how these processes combine with each other.

With regard to species that are chemically related, the nondetection of O₃ and HO₂ in our experiments is consistent with low cometary and ISM measurements. The abundance ratio of HO₂/O₂ for both the 67P and ρ Oph A is 2×10^{-3}

Fig. 5. Striped areas represent relative O_2/H_2O abundances detected in cometary comae of 67P and 1P from Rubin et al. (2019). The data points represent the laboratory experiments presented here. *Left panel:* molecular abundance of O_2 normalised to the amount of H_2O at each UV dose for different initial compositions of the ice. *Right panel:* molecular abundance of O_2 enhanced by the decomposition of H_2O_2 (see text for details).

(Bieler et al. 2015; Parise et al. 2012), while for O_3 there is only an upper limit abundance with respect to O_2 at 2×10^{-5} .

The key discrepancy between our experiments and cometary observations is in the abundance of H_2O_2 . Its formation during UV photolysis is at a similar level to O_2 , which is two orders of magnitude above the observed values (Bieler et al. 2015). An explanation for this might be in an efficient dismutation of H_2O_2 , upon thermal desorption of the water ice as demonstrated by Dulieu et al. (2017). Based on Smith et al. (2011), H_2O_2 is expected to be present in the interstellar ices at an abundance of $(9 \pm 4)\%$ with respect to H_2O and to survive the transfer to the nucleus of the comet. Subsequently, when the comet thermally releases species trapped within the cometary ice, including H_2O_2 , hydrogen peroxide undergoes a dismutation via $2H_2O_2 \rightarrow 2H_2O + O_2$, which is found to produce O_2/H_2O yields from 1 to 10% (Dulieu et al. 2017).

Our experiments are set up such that the abundances we record in the gas phase are a direct measure of the ices. The same may not be the case for the gases observed in the comae around comets 1P and 67P. Therefore, dismutation producing O2 gas from H₂O₂ gas could be a contributing factor to the measured abundance of O₂ in the comets. If O₂ and H₂O₂ ices are produced in similar amounts in the cometary ices (similar to the results from our work), and assuming that all H₂O₂ is processed into O2 (the H2O2 abundance is two orders of magnitude below O_2 in the comet 67P), then the observed abundance of O_2 in the cometary comae may be higher than when it was still in the cometary ice (see also Dulieu et al. 2017; Mousis et al. 2016). If we apply this logic to the experimental yields derived here, then the O₂ abundances are shifted up by the contribution from the H_2O_2 molecules (two H_2O_2 molecules are converted into one O_2). Taking this into account, the experimental values for O₂ abundance (in the gas-phase) for a UV fluence of just under 2×10^{18} photons cm⁻² and an ice mixture of H₂O:CO₂ (100:22) would fall within the observed abundance limits in both comets (see Fig. 5, right panel).

For the O_2 -enriched ices, an increase in the O_2/H_2O ratio is seen for all non-zero UV fluences. It varies between ~3% and ~7%, with the maximum yield at a relatively low UV fluence (based on Fig. C.2). This corresponds to an increase in O_2/H_2O abundance by a factor of 1.5–3.5, relatively to the initial O_2 amount. Following this, it can be argued that the icy material in comets 1P and 67P could have started out (prior to the pre-solar nebula-stage) with a smaller O_2/H_2O ice ratio than seen today. Subsequently, during evolution and if subjected to UV photons (or possibly other energetic processing), the initial ratio could have increased by a factor 1.5–3.5, to explain the ratio that is derived from the Rosina and *Giotto* missions.

It should be noted that UV photolysis is not the only process that affects the composition of the interstellar ices. Other sources of chemical diversity include high-energy particles, X-rays, cosmic rays (CR) themselves, or CR-triggered avalanches of secondary electrons. In the last two decades, the effects of these processes have been investigated via experiments and astrochemical models (Gomis et al. 2004; Zheng et al. 2006a; Mousis et al. 2016, 2018; Eistrup & Walsh 2019; Teolis et al. 2017; Shingledecker et al. 2018, 2019; Notsu et al. 2021). These experimental and modelling findings, combined with our novel results, which may (largely) explain the observed cometary O_2/H_2O ratios, stress the importance of precise chemical modelling. The work presented here now provides explicit values as input parameters.

6. Conclusions

LDPI TOF MS was applied to quantify the formation of O_2 during UV irradiation of simple interstellar ice analogues (H₂O, H₂O:CO₂ and H₂O:CO₂:O₂) at 20 K. The main results are as follows.

- 1. For a UV photon fluence representative of dense molecular clouds and innermost regions of protoplanetary discs (~10¹⁸ photons cm⁻²), UV irradiation of porous amorphous H₂O ice at 20 K leads to formation of O₂ and H₂O₂ in the solid state. The maximum abundances of (O₂/H₂O) and H₂O₂/H₂O are equal to $(0.9 \pm 0.2)\%$ and $(1.3 \pm 0.3)\%$, respectively.
- 2. The mixing of H₂O with CO₂ ice with the ratios 100:11, 100:22, and 100:44 results in an increased relative formation of O₂/H₂O, with a maximum value of $(1.6 \pm 0.4)\%$ for the 100:22 mixture. This also shows that CO₂ is involved in the formation of molecular oxygen.
- 3. The maximum formation efficiency of O₂ and H₂O₂ per energy unit deposited in the pure H₂O ice at 20 K are: $(1.3 \pm 0.3) \times 10^{-3}$ mol eV⁻¹ and $(3.7 \pm 1.0) \times 10^{-3}$ mol eV⁻¹. These yields are similar for the H₂O:CO₂ mixtures; for O₂ it is $(9.7 \pm 0.4) \times 10^{-4}$ mol eV⁻¹, and for H₂O₂ it is $(3.5 \pm 0.9) \times 10^{-3}$ mol eV⁻¹. However, the corresponding maximum photoproduct formation efficiency in the H₂O:CO₂:O₂ mixture are almost an order of magnitude higher; for O₂ it is $(1.1 \pm 0.3) \times 10^{-2}$ mol eV⁻¹, and for H₂O₂ it is $(1.6 \pm 0.4) \times 10^{-2}$ mol eV⁻¹. This is without the contribution of the O₂ already present in the mixture.
- 4. The abundances of O₂/H₂O found in our experiments are sufficient to account for at least part of the observed cometary abundances.

This work demonstrates the potential of MATRI²CES to investigate the photochemical evolution of interstellar ices analogues, including the infrared-inactive species, upon UV photolysis at low temperature.

Appendix A: Abundance of H₂O and CO during UV photolysis

Fig. A.1. Molecular abundance of H_2O normalised to its initial amount as a function of UV photon fluence for different initial compositions of the ice.

The photodepletion of water was derived for all ices investigated in this study and is shown in Fig. A.1. For the pure H_2O ice, the depletion was below the uncertainty related to the initial ice thickness; hence, it was calculated based on the abundances of formed photoproducts. The total abundance of O_2 and H_2O_2 reached $\sim 2 \times 10^{15}$ molecules cm⁻². Under the assumption that each of these species requires two H_2O molecules, the lower limit of water consumption was derived to be $(4.0) \times 10^{15}$ molecules cm^{-2} , which is 4% of the initial column density of the ice.

The formation of CO was derived for all mixed ices investigated in this study, shown in Fig. A.2. Towards the end of UV photolysis, CO was the dominant photoproduct, with a maximum yield in the $H_2O:CO_2:O_2$ (100:22:2) mixture.

Fig. A.2. Molecular abundance of CO as a function of UV photon fluence for different initial compositions of the ice.

Appendix B: UV photolysis of H₂O:CO₂ (100:22 and 100:44)

The mass spectra obtained during the UV photolysis of the $H_2O:CO_2 = 100:22$ and $H_2O:CO_2 = 100:44$ ice mixtures are shown in Fig. B.1 and B.2.

Fig. B.1. LDPI TOF MS signals for a UV-irradiated H₂O:CO₂ ice at 100:22 ratio. The lowest trace in each panel shows the signal without UV irradiation. Peaks at $m/z = 18 \cdot n+1$, where n = 1, 2 represent protonated water clusters formed upon laser desorption of water ice and do not contribute to the chemistry in the ice. The inset shows a zoomed-in image of the intensity scale for the higher masses.

Fig. B.2. LDPI TOF MS signals for a UV-irradiated $H_2O:CO_2$ ice at 100:44 ratio. The lowest trace in each panel shows the signal without UV irradiation. Peaks at $m/z = 18 \cdot n+1$, where n = 1, 2 represent protonated water clusters formed upon laser desorption of water ice and do not contribute to the chemistry in the ice. The inset shows a zoomed-in image of the intensity scale for the higher masses.

Appendix C: UV photolysis of H₂O:CO₂:O₂ (100:22:2)

The mass spectra resulting from the UV photolysis of an H₂O:CO₂:O₂ (100:22:2) mixture are shown in Fig. C.1. The reference mass spectrum (black trace), in addition to the previously described signatures of H₂O and CO₂, also shows the m/z values corresponding to the initial O₂, at m/z = 16 and 32.

After UV irradiation of the ice with a fluence of 6×10^{16} photons cm⁻² (red trace, Fig. C.1), new peaks appear at m/z = 33, 34, and the intensity of features at m/z = 28, 29, 32, and 45 increases. This is representative of the formation of H₂O₂, CO, H₂CO, O₂ and HCOOH. In order to quantify the formation yields of CO and O₂, the signals corresponding to the initial abundances of CO₂ (a fragment overlapping with CO at m/z = 28) and O₂ are subtracted, allowing us to trace the contribution from the newly formed molecules. We note that no H₂ signal is observed until a high UV fluence of 1.9×10^{18} photons cm⁻² is reached.

The abundances of identified photoproducts are calculated following the method described in Sect. 2.2. and are presented in Fig. C.2. The O₂ abundance increases, reaching (4.5 ± 1.1) $\times 10^{15}$ molecules cm⁻². Upon reaching a UV fluence of 2.4 $\times 10^{17}$ photons cm⁻², the O₂ destruction efficiency matches the O₂

formation rate and starts to dominate at higher UV fluence. At a fluence of 3.7×10^{18} photons cm⁻², the O₂ abundance continues to decrease, with a final yield below the initial O₂ abundance.

The formation of H_2O_2 in this mixture follows a trend similar to O_2 . Its abundance reaches a maximum of $(3.5 \pm 0.9) \times 10^{15}$ molecules cm⁻² at 2.4×10^{17} photons cm⁻². Upon longer irradiation, its abundance decreases to $(1.7 \pm 0.4) \times 10^{15}$ molecules cm⁻² at 3.7×10^{18} photons cm⁻².

The quantified consumption of H₂O (Appendix A) is used to derive an upper limit on the relative photoproduct formation (X/H₂O) during the photolysis of H₂O:CO₂:O₂ ices. The upper limit of the relative abundance of (O₂/H₂O) is calculated to be (6.9 \pm 1.6)%, and the corresponding value for (H₂O₂/H₂O) is (5.4 \pm 1.4)%.

The H₂O:CO₂:O₂ (100:22:2) ice at each UV dose absorbs $(25.7 \pm 7.2)\%$ of incident photons. Consequently, the formation yields of O₂ and H₂O₂ reach their maxima equal to $(1.1 \pm 0.3) \times 10^{-2}$ mol. eV⁻¹ and $(1.6 \pm 0.3) \times 10^{-2}$ mol. eV⁻¹, respectively. In comparison to the photolysis of pure water ice and mixtures with CO₂, the formation efficiency (in mol. eV⁻¹) of both products in this mixture is higher by one order of magnitude.

Fig. C.1. LDPI TOF MS signals for a UV-irradiated $H_2O:CO_2:O_2$ ice at 100:22:2 ratio at 20 K. The lowest graph shows the signal without UV irradiation. The inset shows a zoomed-in image of the intensity scale for the higher masses. Peaks at $m/z = 18 \cdot n+1$, where n = 1, 2 represent protonated water clusters formed upon laser desorption of water ice and do not contribute to the chemistry in the ice.

Fig. C.2. Absolute molecular abundances of species during the UV photolysis of mixed ices: $H_2O:CO_2:O_2$ ice at 100:22:2 ratio. Initial ice thickness is (90 ±10) ML.
