ABSTRACT

OBJECTIVE

To evaluate the neurodevelopmental outcome at school age in children newly diagnosed with fetal neonatal alloimmune thrombocytopenia (FNAIT).

STUDY DESIGN

This observational cohort study included children diagnosed with FNAIT between 2002 and 2014. Children were invited for cognitive and neurological testing. Behavioral questionnaires and school performance results were obtained. A composite outcome of neurodevelopmental impairment (NDI) was used, subdivided into mild-to-moderate and severe NDI. Primary outcome was severe NDI, defined as IQ < 70, cerebral palsy Gross Motor Functioning Classification Scale (GMFCS) level \geq III or severe visual/hearing impairment. Mild-to-moderate NDI was defined as IQ 70-85, minor neurological dysfunction or cerebral palsy GMFCS level \leq II or mild visual/hearing impairment.

RESULTS

In total, 44 children were included at a median age of 12 years (range 6-17 years). Neuroimaging at diagnosis was available in 82% (36/44) of children. High-grade intracranial hemorrhage (ICH) was detected in 14% (5/36). Severe NDI was detected in 7% (3/44); in two children with high-grade ICH and one with low-grade ICH and perinatal asphyxia. Mild-to-moderate NDI was detected in 25% (11/44); in one child with high-grade ICH; eight without ICH and in two children neuroimaging was not performed. Adverse outcome (perinatal death or NDI) was 39% (19/49). Four children (9%) attended special needs education, three of whom had with severe NDI and one with mild-to-moderate NDI. Total behavioral problems within the clinical range were reported in 12%, which is comparable to 10% in the general Dutch population.

CONCLUSION

Children who are newly diagnosed with FNAIT are at increased risk for long-term neurodevelopmental problems, even those without ICH.

INTRODUCTION

Fetal and neonatal alloimmune thrombocytopenia (FNAIT), the platelet equivalent of hemolytic disease of the fetus and neonate, can cause severe bleeding in children during pregnancy and shortly after delivery. This risk of bleeding is caused by maternal platelet directed alloantibodies, that are actively transported across the placenta during pregnancy. These antibodies result in platelet destruction and possibly interfere with endothelial cells¹ in the fetus/neonate, resulting in a risk of bleeding. ICH occurs in 10-25% of the cases with severe thrombocytopenia and can be effectively prevented by antenatal treatment.² ³ However, in the absence of antenatal screening for platelet alloantibodies, FNAIT is often diagnosed postnatally, if bleeding symptoms are present or thrombocytopenia is detected as a finding by chance. Effective antenatal treatment is currently only given in subsequent pregnancies.³⁻⁵

Knowledge on long-term outcome of children with FNAIT is scarce. Previous studies primarily addressed the neurodevelopment of children after antenatal treatment for FNAIT,⁶ mainly focused on cases with ICH,⁷⁻¹⁰ or based their conclusions on questionnaire surveys.¹¹ It is important to evaluate neurodevelopment of children only treated after diagnosis of FNAIT and who did not have signs of ICH. This knowledge is crucial to provide adequate follow-up care for children affected by FNAIT and to judge the potential need for an FNAIT screening program.

The present study evaluates the long-term neurodevelopmental outcome of children newly diagnosed with FNAIT. In addition, behavioral difficulties and school performance reports were assessed.

METHODS

PARTICIPANTS

All children newly diagnosed with FNAIT between 2002 and 2014 and referred to the Leiden University Medical Center (LUMC) and survived the neonatal period were eligible for study participation. The LUMC is the national clinical expertise center for FNAIT in The Netherlands. FNAIT was diagnosed based on clinical suspicion with a neonatal platelet level of < 150×10⁹/L and/or bleeding complications, confirmed fetal-maternal HPA incompatibility, and the presence of maternal HPA specific alloantibodies.¹² Children that died perinatally were excluded. Other exclusion criteria were congenital abnormalities not related to FNAIT and the family having moved abroad. The Medical Ethics Committee of Leiden-Delft-The Hague approved the study (P19.069). Written informed consent from all parents or caregivers was obtained. All children provided assent. If children could not assent, parents were asked for permission and the study was conducted unless children opposed participation. The study

CHAPTER 7

was registered at ClinicalTrials.gov (Identifier: NCT04529382). When informed consent was obtained, a one-time follow-up examination was planned, consisting of taking the history, a neurological examination and a standardized intelligence test, either at home or at the outpatient clinic of the LUMC. Parents were asked to complete a questionnaire on their child's behavior and to share school performance results.

METHODS OF MEASUREMENT

The following maternal, obstetrical and neonatal characteristics were obtained from the medical records: gravidity, parity, gestational age at birth (weeks plus days), birth weight (grams), neonatal sex, lowest platelet count, specificity HPA alloantibody, reason for FNAIT suspicion, postnatal treatment, bleeding symptoms, neonatal morbidity including perinatal asphyxia (5-minute Apgar score < 7 or arterial blood cord pH < 7.0) and/or neonatal sepsis (clinical suspicion of infection and positive blood culture), and cerebral imaging report. If the report of the cerebral ultrasound described abnormalities, the images were retrieved and re-evaluated by neonatologists specialized in neonatal cerebral imaging (SJS and LSdV). All scans were scored for intracranial hemorrhage (ICH), including intraventricular hemorrhage (IVH) and/or parenchymal hemorrhage. IVH was classified as any blood in the ventricular system with a distinction between low-grade (small IVH without associated ventricular dilatation) or high-grade (large IVH with associated ventricular dilatation or periventricular hemorrhagic infarction). Parenchymal hemorrhage was classified with a distinction between low-grade parenchymal hemorrhage (hemorrhagic lesions in the brain parenchyma/ cerebellum \leq 4 mm) or high-grade parenchymal hemorrhage (lobar hemorrhages). Highgrade ICH was defined as either high-grade IVH or high-grade parenchymal hemorrhage. Low-grade ICH was defined as low-grade IVH or low-grade parenchymal hemorrhage. Organ bleeding that required supportive care was classified as severe organ bleeding.

Cognitive development was assessed with the Wechsler Intelligence Scale for Children, fifth edition (WISC-V-NL).¹³ The WISC generates a Full Scale Intelligence Quotient (FSIQ) score representing a child's general intellectual ability. The FSIQ is on a standard score metric with a mean of 100 and a standard deviation (SD) of 15. In the Dutch norm population, 13.6% has mild-to-moderate cognitive impairment (IQ 70–85, [-1 SD]) and 2.2% has severe cognitive impairment (IQ < 70, [-2 SD]).13 In case of problems in language and speech development and communication, the Snijders-Oomen nonverbal intelligence test (SON) was performed.¹⁴ Neurological examination was performed according to the adapted version of the Touwen examination, which aims to detect minor neurological dysfunction (MND) and addresses eight neurological domains.¹⁵ Before puberty, the severity of MND, simple or complex, is based on the number of abnormal domains, whereas after puberty it is based on specific abnormal domains.¹⁶ The level of cerebral palsy (CP) was classified using the Gross Motor Functioning Classification System (GMFCS) 17 where a score of 2 or higher was categorized as CP. If lower, a child was categorized as minor neurologic dysfunction.

Behavioral functioning was assessed using the Child Behavior Checklist (CBCL) for 6-18 years.¹⁸ In the present study, internalizing problems score (anxious and depressive symptoms, social withdrawal, and somatic complaints), externalizing problems score (rule-breaking and aggressive behavior), and total problems score were assessed. The CBCL scoring system creates a T-score based on a Dutch normative sample with a mean of 50 and SD of 10, which was interpreted as within the normal (T < 60, < 84th percentile), borderline (T = 60–63; 84th–90th percentile), or clinical range (T \ge 64; \ge 91st percentile).

School performance results were obtained for reading comprehension, spelling, and arithmetic/mathematics according to the Dutch National Pupil Monitoring System (Cito).¹⁹ These results were compared to peers and graded as I through V. Grade I represents the 20% highest scoring children and grade V the 20% lowest scoring children. Additionally, the proportion of children that needed special education was reported.

OUTCOMES

The primary outcome measure was the prevalence of severe neurodevelopmental impairment (NDI), defined as at least one of the following: severe cognitive impairment (IQ < 70, [-2 SD]), CP GMFCS level \geq III, bilateral blindness, and/or bilateral deafness requiring amplification. Secondary outcome measures were mild-to-moderate NDI, total behavioral problem score, school performance, and the overall adverse outcome defined as NDI or perinatal mortality. In addition, we compared the risk of severe NDI between cases with and without ICH. Mild-to-moderate NDI was defined as the presence of one of the following criteria: mild-to-moderate cognitive impairment (IQ 70–85, [-1 SD]), CP GMFCS level I or II, MND, vision loss, and/or hearing loss.

DATA ANALYSES

Data are presented as frequencies and percentages for categorical variables and as means with SD or medians with interquartile range (IQR) for continuous variables. Mean IQ score was compared to Dutch norm data using a one-sample T-test. Mean IQ score was compared between children with and without ICH using a two-sample T-test. The proportion of cases with cognitive impairment, behavior problems and levels of school performance scores were compared to the Dutch norm data using a binominal test. The risk of severe NDI in cases with severe ICH was compared to the risk of severe NDI in cases without severe ICH using the Fisher's Exact test. Clinical characteristics and risk factors for NDI (neonatal morbidity, SGA, gestational age at delivery and/or maternal educational level) were reported for cases with NDI and without NDI. Data were analyzed using IBM SPSS Statistics 26.0 (Chicago, IL, USA). Clinical characteristics of the included children and the children who did not undergo neurodevelopmental assessment were compared to assess selection bias.

RESULTS

STUDY POPULATION

Between 2002 and 2014, 67 cases with newly diagnosed FNAIT were referred to the LUMC (Figure 1). Perinatal mortality occurred in 5 (7%) children: one termination of pregnancy after the diagnosis of severe ICH and hydrocephalus, two children died in utero after ICH, and two in the neonatal period due to severe ICH. In total, 44/56 (79%) children were included for long-term neurodevelopmental assessment.

Abbreviation: FNAIT, fetal and neonatal alloimmune thrombocytopenia;

CLINICAL CHARACTERISTICS AND NEONATAL OUTCOME

Table 1 shows the clinical characteristics of the 44 school-aged children included for longterm follow-up. The majority (80%) had anti-HPA-1a alloantibodies. Children were born at a median gestational age of 38^{+5} (IQR $37^{+3} - 40^{+5}$) weeks with a median birth weight of 3135 (IQR 2610 – 3649) grams. In total, 35 (80%) children were male. Neonatal morbidity occurred in four (9%) children; one child had early neonatal sepsis and three had perinatal asphyxia. The median nadir platelet count was 14×10^9 /L (minimum 2×10^9 /L and maximum 158×10^9 /L), 31 (71%) children had a platelet count below 25×10^9 /L. Characteristics of the included cases were comparable to the cases who did not undergo neurodevelopmental assessment (Supplemental Table 1).

TABLE 1. Clinical characteristics and neonatal outcome

† In two children, ICH was observed during pregnancy after which FNAIT was diagnosed and IVIg treatment was started, in one case at 23 weeks' gestation and in the other child at 30 weeks' gestation (for details see Table 4).

[‡] Neuroimaging was not performed in 8/44 (18%) of the children. In 29/44 children (66%) cerebral ultrasound was performed and in 7/44 children (16%) both cerebral ultrasound and MRI were performed.

§ One case with lung bleeding (severe), one case with gastro-intestinal bleeding (severe) two cases with retinal bleeding (mild) one case with scrotal hematoma (mild).

Abbreviations: HPA, human platelet antigen; FNAIT, fetal neonatal alloimmune thrombocytopenia; ICH, intracranial hemorrhage; IVIg, intravenous immunoglobulins; IQR, interquartile range; SGA, small for gestational age; L, liter.

Neonatal cerebral imaging was performed in 36/44 children (82%). ICH was reported in eight children (22%). Two were classified as high-grade IVH, three as high-grade parenchymal hemorrhage, one as low-grade IVH and, two as low-grade parenchymal hemorrhage. In two children, high-grade ICH was detected antenatally upon routine ultrasound examination (at 23 weeks and 30 weeks of gestational age). In both cases antenatal IVIg treatment was started after HPA-antibodies were diagnosed.

LONG-TERM NEURODEVELOPMENTAL OUTCOME

Long-term neurodevelopment was assessed at a median age of 12 years (minimum 6 years and 5 months and maximum 17 years and 4 months (Table 2)). Overall, NDI was present in 14 (32%) children of which 3 with severe NDI (7%, 3/44, 95% CI: -0.8 – 14%) and 11 with mild-to-moderate NDI (25%, 11/44, 95% CI: 12 – 38%). The overall adverse outcome, NDI or perinatal death, was 39% (19/49, 95% CI: 25 – 54%).

Cognitive assessment with the WISC-V was performed in 41/44 children. The mean IQ score was 100 (SD 14). Due to severe problems in speech and language development, two children were assessed with the SON. IQ scores of these two children were 49 and 60. For one child, the parents did not consent to cognitive testing. Overall, the mean IQ score (98 ± 17) was not different from the general Dutch population norm (100 ± 15; P = 0.420). Mild-to-moderate cognitive impairment was present in 16% (7/43, 95% CI: 5.0 – 28%) and severe cognitive impairment in 5% (2/43, 95% CI: -1.8 – 11%).

Neurological testing was completed in 41 children (93%). MND was detected in eight children of which four children presented with simple MND (10%, 95% CI: 0.5–19%) and four with complex MND (10%, 95% CI: 0.5–19%). CP was observed in two children (5%, 2/41, 95% CI: -1.9 - 12%), one with spastic diplegia and one with spastic tetraplegia, both classified as GMFCS level IV. One child (2%) was diagnosed with bilateral deafness requiring hearing amplification, related to perinatal asphyxia. The cause of perinatal asphyxia in this child remained unclear.

Table 3 presents the details of the children with NDI. Of the three children with severe NDI, one was diagnosed with high-grade IVH and one with high-grade parenchymal hemorrhage. The third child with severe NDI was diagnosed with bilateral deafness, postnatal MRI showed cerebral edema related to perinatal asphyxia and (low-grade parenchymal hemorrhage). Of the 11 children with mild-to-moderate NDI, one was diagnosed with high-grade IVH, eight children did not have cerebral hemorrhage and in two children no brain imaging was reported. Two cases with high-grade ICH had a normal neurodevelopmental outcome. Both cases that had no NDI despite high-grade ICH had an unilobular parenchymal hemorrhage whereas in the group of children that had NDI and high-grade ICH, two had periventricular hemorrhagic infarction and one had a multilobular parenchymal hemorrhage. An overview of the neurodevelopmental outcome of the 44 FNAIT cases is shown in Figure 2.

‡Based on the information of the school results and questionnaires that were completed by the parents or caregivers, we categorized the missing cognitive test scores as normal.

§ Neurological test was not performed in 3/44 (7%) children due to no permission.

|| Both children with CP were classified as a Gross Motor Functioning Classification Scale (GMFCS) level IV. One child had spastic diplegia, the other spastic tetraplegia.

Based on the information of the school results and questionnaires that were completed by the caregivers, we categorized the missing scores needed for NDI as normal.

Abbreviations: IQR, Interquartile range; IQ, intelligence quotient; SD, standard deviation; MND, minor neurological dysfunction; CP, cerebral palsy; NDI, neurodevelopmental impairment.

FIGURE 2. Neurodevelopmental outcome of 44 FNAIT cases

Abbreviations: NDI, neurodevelopmental impairment; ICH, intracranial hemorrhage.

Children with high-grade ICH had significantly lower cognitive scores compared to the children without high-grade ICH (median IQ 65 (range 49 – 106) versus 99 (range 76 – 129) respectively, P = 0.027). In total, 40% (2/5) of cases with high-grade ICH had severe NDI versus 3% (1/38) of cases without high-grade ICH (relative risk 15.6, 95% CI 1.7 – 142.6, P = 0.030). In 50% (7/14) of the cases with NDI, other risk factors for NDI were present compared to 20% (6/30) in the cases without NDI. Clinical characteristics of the cases with and without NDI are shown in Supplemental Table 2. Within the group of cases that had NDI, the majority (71%, 10/14) were affected by anti-HPA-1a. Of the four children affected by other HPA specific antibodies two had high-grade ICH, one was affected by perinatal asphyxia and one was born SGA.

BEHAVIORAL FUNCTIONING AND SCHOOL PERFORMANCE

Five out of 41 children (12%) scored in the clinical range (T score \geq 91st percentile) on the total problem score of the behavioral questionnaire (Supplemental Table 3). School performance scores were available for 43/44 (98%) children (Supplemental Table 3). The prevalence of the children scoring the lowest level V range did not differ significantly from the Dutch norm population. Four children (9%, 4/44) attended special needs education, of which three had high-grade ICH.

DISCUSSION

This study shows that children newly diagnosed with FNAIT and who survive the neonatal period have a high risk of long-term neurodevelopmental impairment (NDI). Severe NDI was present in 7% and mild-to-moderate NDI in 25%, thus combined nearly one-third of the children had long-term neurodevelopmental problems. The overall adverse outcome, perinatal mortality or NDI, was 39%.

The risk of severe NDI in children with newly diagnosed FNAIT is especially high among those with high-grade ICH. In our cohort severe NDI was observed in two children with high-grade ICH and one child with low-grade ICH and cerebral injury related to perinatal asphyxia. This is in line with a previous study from our group that reported on the neurodevelopmental outcome after ICH due to FNAIT. In this study, severe and mild-to-moderate NDI was diagnosed in 60% (6/10) and 10% (1/10) of the FNAIT survivors with ICH, respectively.⁷ In an international cohort study of 43 children with FNAIT-related ICH, 82% of the children that survived had severe neurological disabilities.¹⁰ In our cohort, two cases with high-grade ICH had normal neurodevelopmental outcome, this finding fits in with previous literature in which children can have normal neurodevelopment despite severe brain hemorrhage.²⁰ We hypothesized that the neurodevelopmental outcome of newly diagnosed children would be worse than the general population, independent of the presence of ICH. This expectation was based on increasing evidence that the maternal alloantibodies in FNAIT cause platelet destruction and possibly interfere with endothelial cells.^{1, 21} Possibly, this leads to small cerebral bleeding and/or impaired (cerebral) angiogenesis that remain subclinical directly after birth, but affect brain development leading to developmental delay on the long term.²² Alternatively it could be that fetal thrombocytopenia irrespective of the presence of anti-HPA-1a influences brain development.

Within our study, we found mild-to-moderate NDI in 25% of the children of whom only one was diagnosed with high-grade ICH. This percentage was higher than one would expect in the normal population. Half of the children that were classified as mild-to-moderate NDI were diagnosed with MND. In general, the proportion of complex MND (10%) in our study group was slightly higher compared to the 6% in Dutch school aged children.¹⁵ Possibly, the high proportion of children with MND is related to subclinical cerebral damage, that remained undiagnosed short after delivery but led to mild and/or multiple neurodevelopmental problems in the long-term. Alternatively, the higher proportion of children with MND could be explained by the unequal sex distribution in our study group. In accordance with previous cohort studies on FNAIT,^{23, 24} we observed an overrepresentation of boys in our cohort. However, these previous studies found a more balanced gender distribution compared to our cohort. Both simple and complex MND are diagnosed two times more often in male children compared to female children. Possibly the high rate of NDI could be related to the

relative higher risk of MND in male infants; 13 of the 14 children with NDI were male. Besides the overrepresentation of male sex, we observed that in 50% of the cases with NDI other risk factors for NDI were present whereas in the cases without NDI this was only in 20%. Unfortunately, an independent risk factor analysis to identify these factors was not possible due to our limited sample size. In addition, SGA, neonatal morbidity and low maternal education level are closely intertwined. HPA-1a immunization was reported to be associated with reduced birthweight in other cohort studies.^{24, 25}

Previous studies have described the neurodevelopmental outcome of newly diagnosed children with FNAIT. Ward et al.¹¹ concluded that newly diagnosed children had a worse long-term outcome than their IVIg-treated siblings, but this was based on a behavioral questionnaire taken over the phone with a loss to follow-up of 32%. Knight et al.²⁶ conducted a study based on obstetric and pediatric surveillance data in the United Kingdom on children with FNAIT. In this study, 8% of the children newly diagnosed with FNAIT had a disability. However, this study was limited by a follow-up to only one year of age. The percentage of 8% disability seems lower than in our study yet was based on national surveillance data and not on standardized individual assessments and the definition of disability was not clearly described.

The proportion of children diagnosed with cerebral palsy in our study was higher than in the general population, 5% versus 0.2%²⁷ Both children with cerebral palsy had an antenatally acquired ICH. In total, 9% of the children were in special needs education, which is more than the regular population.²⁸

This study shows that children with FNAIT without ICH may be at risk of mild-to-moderate long-term impairment, yet the risk of mortality and severe impairment is especially high for children with ICH. These findings stress the importance of preventing severe bleeding in FNAIT and therefore the development of assays that can identify pregnancies at risk for bleeding within HPA alloimmunized pregnant women. By identification of these pregnancies, antenatal treatment could prevent the occurrence of ICH and cerebral injury and thereby the associated adverse outcome.

The knowledge provided by this study will be of help for obstetricians and neonatologists counselling parents of a child affected by FNAIT. FNAIT survivors are at risk of neurodevelopmental problems, in particular children affected by ICH. To improve the neurodevelopment of children affected by FNAIT that were not antenatally treated with IVIg, adequate follow-up care should be provided. Additionally, the results of our study underline the importance of performing neuroimaging in children newly diagnosed with FNAIT.

CHAPTER 7

A limitation of this study is the absence of a control group. Yet, by using standardized tests based on a normative sample, it is possible to compare the results to the population norms. Another limitation is that not all eligible children were included in the study since 21% of the eligible children did not undergo neurodevelopmental assessment. However, when comparing the included children to those who did not undergo neurodevelopmental assessment, the clinical characteristics were similar. Although most parents or caregivers did not specify the reason for not wanting to participate, some indicated that it had to do with being confronted with the disease again or participation asking too much effort. One further constraint of our study was that it was a single center study including only children referred to the LUMC. Between 2002 and 2014 195 children were diagnosed with FNAIT at our national reference laboratory (Sanguin) of which 67 (34%) were referred to the clinical expertise center (LUMC). A strength of the current study is that it is the first to assess the long-term neurodevelopmental outcome of children newly diagnosed with FNAIT using standardized psychometric tests, neurological tests and incorporating school performance results. In addition, our study included children at an older age than in previous studies, thereby providing a more reliable and accurate view of the long-term development of these children.

In conclusion, children newly diagnosed with FNAIT who survive the neonatal period are at high increased risk of long-term neurodevelopmental problems and therefore should have postnatal neuroimaging and be monitored adequately in a standardized follow-up program. Severe neurodevelopmental impairment and mortality is predominantly observed among children with ICH. In addition, a quarter of the children in this cohort suffer from mild-to-moderate impairment suggesting that the risk of NDI is high also in children without ICH.

ACKNOWLEDGMENTS

We would like to thank Marleen van der Berg (MSc), Tijn Borm (MD), and Fleur Derks (MD), all involved from within the Willem-Alexander Children's Hospital during (part of) the study period, for their dedicated work in approaching families and follow-up assessments.

SUPPLEMENTAL TABLE 1. Comparison of characteristics of children undergoing and excluded from neurodevelopmental testing

Characteristics of the children included in the study were compared to the surviving FNAIT children who did not undergo neurodevelopmental assessment. Analysis was performed using the Mann Whitney *U* test (gestational age, birth weight, and platelet count) or with the Fisher's Exact Test (categorical variables). No statistically significant differences were found. † Data available for 36/44 (82%) children. From the children who did not undergo neurodevelopmental assessment it was not known whether neuroimaging was performed or not.

‡ Data available for 9/12 (75%) children.
