Chapter 6 Comparing the effectiveness of Cognitive Behavioral Therapy-Enhanced between patients with different Eating Disorder classifications: a naturalistic study

Published as Melisse, B., Dekker, J., Berg, E. v. d., Jonge, M. d., Koenders, J., Peen, J., & Beurs, E. d. (2022). Comparing the effectiveness and predictors of cognitive behavioural therapy-enhanced between patients with various eating disorder diagnoses: a naturalistic study. *The Cognitive Behaviour Therapist*, 15. [https:// doi.org/10.1017/S1754470X22000174](https://doi.org/10.1017/S1754470X22000174)

Abstract

Introduction: Cognitive behaviour therapy-enhanced (CBT-E) is an effective treatment for non-underweight patients with eating disorders. Its efficacy and effectiveness is investigated mostly among transdiagnostic samples and remains unknown for binge eating disorder. The aim of present study was to assess several treatment outcome predictors and to compare effectiveness of CBT-E among adult outpatients with bulimia nervosa ($N=370$), binge eating disorder ($N=113$), and those with a restrictive food pattern diagnosed with other specified feeding and eating disorder ($N=139$).

Method: Effectiveness of CBT-E was assessed in routine clinical practice in a specialised eating disorders centre. Eating disorder pathology was measured with the EDE-Q pre- and post-treatment, and at 20 weeks follow-up. Linear mixed model analyses with fixed effect were performed to compare treatment outcome among the eating disorder groups. Several predictors of treatment completion and outcome were examined with a regression analysis.

Results: No predictors for drop-out were found, except the diagnosis of bulimia nervosa. Eating disorder pathology decreased among all groups with effect sizes between 1.43-1.70 on the EDE-Q total score. There were no differences in remission rates between the three groups at end of treatment or at follow-up. Eating disorder severity at baseline affected treatment response.

Discussion: The results can be generalised to other specialised treatment centres. No subgroup of patients differentially benefited from CBT-E supporting the transdiagnostic perspective for the treatment of eating disorders. Longer-term follow-up data are necessary to measure persistence of treatment benefits.

Keywords: Cognitive Behaviour Therapy-Enhanced, Eating Disorders, Bulimia Nervosa, Binge Eating Disorder, Other Specified Feeding and Eating Disorder

Key learning aims

- (1) What is the effectiveness of CBT-E among patients suffering from binge eating disorder?
- (2) Does any subgroup of patients suffering from an eating disorder differentially benefit from CBT-E?
- (3) What factors predict treatment response?

Introduction

Eating disorders, which have a significant impact on the well-being of patients (Hay et al., 2015), have a life-time prevalence of about 2% (Preti et al., 2009). Since such disorders are moderately responsive to psychological interventions, to enhance recovery rates and minimize negative consequences, the effectiveness of various treatments needs to be investigated for each eating disorder (Linardon, Wade, et al., 2017). The National Institute for Health and Care Excellence guidelines recommends cognitive behaviour therapy for eating disorders (NICE, 2017). One such evidence-based treatment is cognitive behavioural therapy-enhanced (CBT-E) (Fairburn, 2008).

CBT-E is based on a transdiagnostic model which assumes that all eating disorders share common core mechanisms (Cooper & Fairburn, 2011; Fairburn et al., 2003). CBT-E addresses these mechanisms such as over-evaluation of shape, weight and eating (Fairburn et al., 2003). However, data regarding over-evaluation of shape and weight among patients suffering from BED are inconclusive (Coffino, 2019; Linardon, 2017). Still it is assumed that all eating disorder patients with a BMI between 17.6 and 39.9 can be treated with a similar treatment (Fairburn, 2008; Fairburn et al., 2003).

CBT-E is effective among transdiagnostic samples, for patients suffering from bulimia nervosa (BN), and other specified feeding and eating disorder with a restrictive food pattern (OSFED). However, though patients suffering from binge eating disorder (BED) were included in transdiagnostic samples, no remission rates of individually offered CBT-E among adult patients suffering from BED have been reported. Remission rates based on reduction in eating disorder pathology vary between 18-70%. Full recovery, defined as abstinence of eating disorder behaviours and eating disorder pathology below clinical cut-off, varies between 14.3-50% (Supplementary Table A). Treatment response of CBT-E differ substantially at the end of treatment (EOT) and at follow-up (Berg et al., 2020; de Jong et al.,

2018; Linardon, Wade, et al., 2017). This suggests that the effectiveness of CBT-E can be improved.

Determining treatment outcome predictors of CBT-E enables prognostic information about whom CBT-E is likely to work for. Treatment outcomes can be maximized by an understanding of its predictors because more targeted and intensive treatment can be offered, thus improving clinical decision making, allowing for personalized medicine, so potentially enhancing treatment outcome (Kraemer, 2013). Although consistent findings on predictors of CBT-E are scarce, poorer treatment outcome was predicted by a lower BMI and higher frequency of eating disorder behaviours at start, longer duration of the eating disorder, and having received eating disorder treatment in the past (Cooper et al., 2016; Linardon, de la Piedad Garcia, et al., 2017; Linardon, Wade, et al., 2017; Vall & Wade, 2015).

This study involves an observational design, comparing treatment responses of BN, BED, their respective OSFED and OSFED with a restrictive food pattern, and applying alternative categorisations of clusters of diagnosis. Comparisons were made for treatment delivered in everyday clinical practice by routine outcome monitoring at fixed time intervals (de Beurs et al., 2011). Effectiveness studies tend to include a more heterogeneous patient population (Knott et al., 2015; Waller et al., 2014), including patients with complex and comorbid disorders (Leichsenring, 2004).

Data are scarce on how adult patients classified with BED respond to CBT-E when offered it individually (Berg et al., 2020; Byrne et al., 2011; Fairburn et al., 2015; Fairburn et al., 2009). Examining whether the specific eating disorder diagnosis matters enables to investigate if CBT-E works for all eating disorders. Part of the sample in this study was included in a transdiagnostic study by Van den Berg et al., (2020). The present study involves a larger sample, thus increasing statistical power and allowing investigation of several outcome predictors, including eating disorder diagnosis. To our knowledge, no previous

studies have compared the effectiveness of CBT-E for different eating disorders. Furthermore, with the exception of adolescents and group settings, remission rates for BED specifically have not been previously reported on (Dalle Grave et al., 2015; Wade et al., 2017).

The aim of present study is to compare effectiveness of CBT-E in various eating disorder subtypes, and to investigate the predictive value of potential prognostic variables for outcome. It is hypothesized that eating disorder pathology declines among all groups, and that poorer treatment response is predicted by greater eating disorder severity, higher frequency of eating disorder behaviours, and a lower BMI at baseline, having received an eating disorder treatment in the past, and longer duration of the eating disorder. Secondary eating disorder pathology and general psychopathology are expected to decrease at EOT and follow-up.

2 Methods

2.1 Design

This study had a cohort design, using between-group comparisons of patients with various eating disorder subtypes. Of the patients who received treatment for eating disorders from 1 July 2015 till 31 December 2019 at a Dutch specialised centre for eating disorders and obesity, 625 were eligible for inclusion and constituted the intent-to-treat sample. Treatment outcomes of 294 participants with a BMI between 17.6-39.9 who received treatment between 1 July 2015–31 December 2017 were also included in Berg et al., (2020). In contrast, in current study, therapy outcomes between three groups, namely BN and BED (including their respective OSFED), and OSFED with a restrictive food pattern were compared. Alternative categorisations of diagnosis were: comparing treatment outcomes for BN, BED, OSFED, OSFED BED, and OSFED BN, and: comparing one OSFED group to the BN and BED groups. Patients were assessed at start and EOT. A follow-up assessment took place 20 weeks

after conclusion of the treatment. Patients did not receive additional treatment in the follow-up period but were put on a waitlist awaiting further treatment related to other psychopathology. Patients who did not complete CBT-E phase three (less than 18/22 treatment sessions) were considered non-completers. Completion of the final phase of the treatment (“ending well, session 19-22”) was not required to be deemed a completer. Thus, patients who completed at least 18 of the 22 treatment sessions were considered completers.

Figure 1 presents a flowchart of data collected.

2.2 Participants and Recruitment

Patients were recruited at Novarum after referral by their general practitioners or other clinicians. Patients were diagnosed with an eating disorder after a semi-structured clinical interview by a psychiatrist or clinical psychologist, ≥ 18 years, were fluent in either Dutch or English, and had BMI (kg/m^2) ≥ 17.5 and < 40 . Patients were included if they met DSM-5 criteria for an eating disorder (APA, 2013). Uncertainties about diagnosis were resolved by team discussion. Severity of eating disorder pathology and weight were both determined at the start and at the EOT. Patients were excluded if diagnosed with another psychiatric disorder needing immediate attention (e.g., acute psychosis, severe alcohol or drug abuse, or suicidal ideation).

2.3 Measures

2.3.1 Eating disorder Pathology: EDE-Q 6.0

The EDE-Q (Fairburn & Beglin, 2008), a self-report questionnaire, was used to determine eating disorder behaviours as well as general eating disorder pathology over the past four

weeks. The EDE-Q has 28 questions measured on a 6-point Likert scale. The Dutch version of the EDE-Q, which has good psychometric properties, was used (Aardoom et al., 2012). Cronbach's α of the Dutch version of the EDE-Q was 0.95 and 0.86 in present study.

For remission, a cut-off score of 2.77 on the EDE-Q global score was used, because it represents the portion of patients with a global score below the international community mean plus one standard deviation. Full recovery was defined as EDE-Q global score <2.77 and no additional eating disorder behaviours (binging, purging, laxatives, exercising) during the last month and $BMI \geq 18.5$. Clinically significant change (CSC) was defined as reliable change together with an EDE-Q global score <2.77 . Reliable change index (RCI) was established as 0.69 change on the EDE-Q global score (Jacobsen & Truax, 1991).

2.3.3 Clinical Impairment Assessment

The Clinical Impairment Assessment (CIA) measures secondary impairment due to eating disorder pathology, measured at personal, social and cognitive areas of life (Bohn et al., 2008). The CIA is a self-report questionnaire, 16 items are rated on a 4 point Likert scale. The Dutch translation has good psychometric properties, Cronbach's α was 0.91 and 0.92 in present study. CIA total score was used as measure of severity.

2.3.3 Psychological and social functioning: Outcome Questionnaire 45

The Outcome Questionnaire 45 (OQ-45) is a self-report questionnaire measuring psychological and social functioning, including symptom distress (25 items), interpersonal relations (11 items), social role (9 items) and anxiety and social distress (13 items) over the past week. The items are measured on a 5-point Likert scale. The Dutch version has good

psychometric properties (Timman, 2017). The Dutch version has an α between 0.91-0.93 (de Jong, 2007) and was 0.70 in present study. OQ-45 total score was used as measure of severity.

2.3.4. The Depression Anxiety and Stress Scales

The Depression Anxiety and Stress Scales (DASS) is self-report questionnaire consisting of three subscales of 14 items to assess depression, anxiety, and stress. All 42 items are rated on a 4-point (0–3) Likert scale. The Dutch translation of the DASS has good psychometric properties and an α between 0.85-0.94 (de Beurs, 2001). Cronbach's α was 0.84 in present study. DASS total score was used as measure of severity.

2.3.5 Demographics

Demographic characteristics, including age, gender, marital status, domestic situation, level of education and occupational status, were gathered by self-report before the start of treatment.

2.5 Intervention

All patients received individually delivered outpatient CBT-E treatment (focused version), as extensively described in the CBT-E manual. CBT-E consists of 21 sessions of 50 minutes, over a 20-week period. In order to discuss further progress, a review session was offered twenty weeks after EOT (Fairburn, 2008).

2.6 Therapists

Therapists delivering CBT-E had various professional backgrounds (psychologists, psychiatrists, nurse practitioners, dieticians), and educational levels (bachelors degree, masters degree, post-doctoral degree). A web-based CBT-E training provided by the Centre for Research on Eating Disorders at Oxford (CREDO) was successfully completed by all therapists, and they studied the detailed CBT-E manual (Fairburn, 2008). To ensure adherence and familiarize themselves with CBT-E, all therapists attended weekly one-hour peer supervision sessions supervised by senior therapists.

2.7 Statistical analysis

SPSS version 25 was used for statistical analysis. To determine whether baseline scores and demographics (age, gender, level of education, eating disorder severity) predicted treatment completion, chi-square analyses for categorical variables and binomial logistic regression for dimensional variables were used. Significance of baseline differences between the eating disorder groups were examined with chi-square tests or ANOVA. Reduction in eating disorder pathology from start to EOT and 20 weeks follow up was analysed with a repeated measures ANOVA. Within group effect sizes were calculated using Cohen's d (0.2 small, 0.5 medium, 0.8 large) (Cohen, 1977) and adjusted for bias (Hedges, 1981). Bivariate and multiple regression analyses were performed to determine treatment outcome predictors with eating disorder pathology severity as dependent variable. To enhance power, the predictors were investigated on the continuous outcome variable of eating disorder severity as measured by the EDE-Q at EOT and at 20 weeks follow-up. Post-hoc calculated power, considering an effect size of 0.26, $\alpha = 0.05$ (2 sided), was 100%. Outliers were removed when scores were more than three standard deviations above or below the means: at the start two EDE-Q scores between 0.52-0.65, a score of 118 objective binge episodes, and a score of 140

times self-induced vomiting were removed. Linear mixed model analyses with fixed effect at the individual level were performed to examine the effect of diagnostic group on EDE-Q score at start, EOT, and at follow-up. The groups were nested in their diagnostic group (BN, BED, OSFED), and fixed effects were age and gender. The interaction between EDE-Q scores, eating disorder classification and the fixed effects were also measured. The contrasts chosen compared BN (reference group) to the BED and OSFED group. Second, the OSFED as reference group was compared to the BED and BN group. Last, the BED (reference group) was compared to the OSFED and BN group. All contrasts were compared at start, EOT and follow-up. Analyses were primarily performed according to an intention-to-treat approach (imputed dataset with 50 imputations for each missing observation), which included all patients with 29% missing data, and additionally on completers only (complete assessments available at baseline and EOT). Imputations were performed by the multiple imputation by chained equations using predictive mean matching. Multiple imputation was used for missing outcome data, under a missing-at-random assumption: analyses were first performed on the imputed datasets separately, then the outcomes of the 50 imputations were combined using Rubin's rules (Rubin, 2004).

2.8 Ethics

All patients were informed about the study, assured that their data were de-identified, and all signed an informed consent form, in accordance with the World Medical Association Declaration of Helsinki (World Medical Association, 2001). According to the Dutch Central ethical Commission on Medical Research with human subjects (Dutch abbreviation: CCMO) analysis of anonymized routine outcome monitoring data does not require additional approval from a local medical-ethical approval board.

3 Results

Figure 1. Flowchart of patients in study

EOT end of treatment, *FU* follow-up, *OSFED* Other specified feeding and eating disorder

3.1 Patient flow

Figure 1 shows that, of the 986 patients originally considered for CBT-E, 277 were excluded because they did not meet the inclusion criteria based on BMI. A further 84 were not included in the initial sample because they did not finalize their 22 treatment sessions within study time period. The study therefore included 625 patients, 370 of whom met criteria for BN (BN: $N=259$, OSFED BN: $N=111$), 113 for BED (BED: $N=39$, OSFED BED: ($N=74$), and 142 met criteria for OSFED ($N=142$). Only relationship status, gender and dietary restraint differed at baseline between groups at a $p=0.05$ significance level. The BED group included more males and had a significantly lower dietary restraint score, and the OSFED group were less in a relationship (Table 1).

3.2 Treatment completion and compliance regarding the assessments

Of the 625 patients who started treatment, 391 (62.6%) completed the full course of treatment and showed compliance regarding completing the assessments (OSFED: $n=101$, completion rate 71.1 %; BN: $n=208$, 56.2 %; BED $n=82$, 72.6 %). Non-completers completed on average 12,4 (SD= 4.10) sessions. Completion rate was significantly lower in the BN group ($\chi^2=18.6$, $p=.006$). Loss to therapy was not predicted by age, waiting list duration, baseline EDE-Q global score, frequency of objective and subjective binge eating, vomiting, laxative misuse, intensive exercising, and BMI. Compliance with the 20 weeks post treatment follow-up assessments was 80.3% (BN 93.8%, BED 56.1%, OSFED 72.2%). Chi-square analyses revealed no differences between subgroups with regard to compliance at follow up ($\chi^2=2165.6$, $p=.790$).

$p < .05$ indicates a statistical significance according to a χ^2 -test or ANOVA

3.3 Remission

3.3.1 Intention to treat analysis

The intention-to-treat analysis was performed on the imputed dataset ($N= 625$, BN: $n= 370$, BED: $n= 113$, OSFED: $n= 142$). Table 2 shows that a repeated measures ANOVA revealed statistically significant improvements on the EDE-Q total score in all groups between start and EOT and start and follow up (Table 2). Since sphericity was violated in the BN group, the degrees of freedom were corrected by Huynh-Feldt estimates ($\epsilon = 180.90$, $p=.005$). Effect sizes for all groups were large on the EDE-Q total score (BN: $d=1.70$, BED: $d=1.44$, OSFED: $d=1.43$). Eating disorder behaviours did not always decline significantly, all eating disorder behaviours diminished only significantly in the BN group. BMI only changed in the OSFED group at EOT. Secondary eating disorder pathology and general

psychopathology reduced at EOT and follow-up, except for secondary pathology in the OSFED group at EOT.

Table 2

Remission varied between 34.2%-65.2%). Full recovery was 0-37% and clinically significant change varied between 24.4-58.7% (Table 3).

Linear mixed model analysis with fixed effects showed no differences in remission based on the EDE-Q between the three groups ($p>.05$). Alternative categorisations of diagnosis did not yield different results: additional linear mixed model analysis with fixed effects showed that there were also no differences between groups ($p>.05$) when all OSFED ($N = 327$) patients were categorised in one group and the BN ($N = 259$), and BED ($N = 39$) group consisted only of BN and BED patients respectively, no differences were found ($p>.05$). There were also no differences between groups ($p>.05$) when patients were categorised in five groups (BN; $N= 259$, OSFED BN; $N= 111$, BED; $N= 39$, OSFED BED; $N= 74$, OSFED; $N= 142$).

¹ Full recovery: EDE-Q < 2.77, BMI > 18.5 and no eating disorder behaviours (binges, self-induced vomiting, laxative misuse, extensive exercising)
 CSC clinical significant change, EOT end of treatment, FU follow up,
 NA not applicable, RCI reliable change index

3.3.2 Completer analyses

All analyses were repeated on the data of the completers sample. There were no substantial differences between the results of the intention-to-treat analysis and the completers analysis. All groups showed statistically significant improvements on the EDE-Q between start and EOT and start and 20 weeks follow up. There were no further improvements or declines between EOT and follow-up. Effect sizes for all groups were large on the EDE-Q total score (OSFED: $d=1.31$; BN: $d=1.74$, BED: $d=1.46$). However, among the BED group the results of the intention-to-treat analysis were favourable over the completers regarding remission based on $EDE-Q < 2.77$ (65.2% vs 55.8%), and full recovery (37.0% vs 24.6%).

3.4 Predictors of treatment outcome

In the intention-to-treat sample, higher level of education predicted better outcomes on EDE-Q total score at EOT ($r = -0.14$, 95% CI= -0.03-0.03, $p=0.028$) and males had better outcomes at follow-up ($r = 0.18$, 95% CI= 0.95-2.10, $p=0.021$). However, these associations were not substantial (See for a full account of the findings regarding predictors supplementary materials Table B).

Clinical predictors of treatment outcome regarding EDE-Q total score were investigated in the entire sample and separately for the three subgroups (if not significant for subgroups, only results for the entire sample are reported). In the intention-to-treat sample only severity of eating disorder pathology at baseline was a predictor for eating disorder severity at EOT for the complete sample ($r = 0.51$, 95% CI= 0.56-0.77, $p < 0.001$), OSFED ($r = 0.70$, 95% CI= 0.59-0.96, $p < 0.001$), BN ($r = 0.45$, 95% CI= 0.51-0.82, $p < 0.001$) and BED ($r = 0.43$, 95% CI= 0.20-0.77, $p < 0.001$).

Baseline EDE-Q score predicted eating disorder severity at follow-up for the entire sample ($r= 0.55$, 95% CI= 0.64-0.82, $p<0.001$), for BN ($r= 0.47$, 95% CI= 0.44-0.89, $p=0.021$) and OSFED ($r= 0.72$, 95% CI= 0.59-1.14, $p=0.021$), not for BED ($p>0.05$). BMI and frequency of eating disorder behaviours at baseline, duration of the eating disorder, and having been treated before did not predict treatment outcome ($p>0.05$) in any of the groups (Supplementary materials Table C).

Discussion

The aim was to determine and compare the effectiveness of CBT-E for non-underweight adults, differentiating between BN, BED, their respective OSFED, and OSFED outside the confines of an RCT. Severity at start was higher in the present study compared to other studies (Byrne et al., 2017; Poulsen et al., 2014; Wonderlich et al., 2014). Eating disorder pathology declined significantly and clinically significant change ranged between 24.4-58.7%.

With regard to the various types of remission there were no differences in treatment outcomes between the completers sample and the intention-to-treat sample, therefore, patients might also recover with a less intense form of treatment (Berg et al., 2020; Moore et al., 2021; Waller et al., 2018). Only eating disorder severity at start significantly predicted outcome. Consistent with a transdiagnostic perspective on eating disorder treatment, eating disorder diagnosis did not predict treatment outcome regarding overall pathology and full recovery.

The results of the present study replicated the findings of a transdiagnostic treatment effect by van den Berg et al (2020). Remission and full recovery rates were comparable with other effectiveness studies, while effect sizes on the EDE-Q were larger compared to other effectiveness studies (Byrne et al., 2001; Knott et al., 2015; Wade et al., 2016; Dalle Grave et

al., 2015). In addition, compared with trial studies effectiveness was somewhat lower (Supplementary Table A) (Fairburn et al., 2009; Fairburn et al., 2015).

Contrary to expectations, a lower BMI and higher frequency of eating disorder behaviours at start, longer duration of the eating disorder, and treatment in the past did not predict treatment outcome among the complete group, nor in any of the subgroups. Based on the results, it was generally not possible to identify a subgroup of patients who especially benefit from CBT-E.

Explanations why the present results regarding treatment outcome predictors differed from previous studies: first, the effect sizes of predictors, such as duration of the eating disorder, BMI (Vall & Wade, 2015) and eating disorder severity (Linardon, de la Piedad Garcia, et al., 2017) were small in other studies. Although some studies found eating disorder behaviours to predict treatment outcome, due to the large variations in the reported effects, a meta-analysis did not find their frequency predicted treatment outcome (Vall & Wade, 2015). The use of different definitions may also have impacted research on the prediction of outcome. For instance, Cooper et al (2016) investigated the prognostic effect of eating disorder duration by categorizing duration as greater or less than eight years, while this study investigated duration as a continuous variable. BMI may not have predicted treatment outcome in the present study because in the present study underweight patient were excluded. Other studies, which found that BMI predicted treatment outcome did include, underweight patients (Linardon, de la Piedad Garcia, et al., 2017; Vall & Wade, 2015). Investigation into the prognostic roles of higher levels of self-esteem (Cooper et al., 2016), impulsivity, depression (Castellini et al., 2012) and lower levels of self-control, discrepancy of actual and ideal self (Anderson et al., 2020) when offering CBT-E is also recommended because they predicted poorer treatment outcome when offering eating disorder treatment.

Overall, treatment completion and compliance to the assessments was 62.6%, and the lowest in the BN group. Treatment completion rate was comparable to other effectiveness studies, with rates between 36.3%-50% (Byrne et al., 2011; Knott et al., 2015; Signorini et al., 2018). In addition, the loss to therapy rate of 37% may have been affected by the fact that treatment payment was covered by the patients' health care insurance. In addition, efforts to ensure patients complete treatment may be more limited in effectiveness studies than in an efficacy studies (Byrne et al., 2011). In addition, since more than 50% of all patients showed compliance regarding the assessments, the results can be generalised to other eating disorder patients (de Beurs et al., 2019). Motivational sessions prior to commencing treatment might reduce dropout and enhance treatment completion among patients suffering from BN.

The limitations of the present study are as follows: our findings do not reveal whether long-term recovery was attained, as that requires a longer period of 20 weeks. Unfortunately, compliance towards the assessments was less than 30% at 60 weeks follow-up. The response rate diminishes with a longer follow-up duration, as patients are less committed to provide these data. Since response rate at follow-up was about 50%, results might be biased to patients who responded well to treatment or who relapsed. Another limitation was that outcome data were limited to patients' self-report. There was low concordance between self-reported eating disorder behaviours in the EDE-Q at baseline and during the semi-structured interview at the intake session. An increase in awareness of eating disorder symptomatology over time may lead to a higher score on the EDE-Q, diminishing the pre-to post-test change resulting from treatment (Berg et al., 2013). On the other hand, as self-report measures are most widely used, they provide data on treatment outcome in everyday clinical practice. In addition, effectiveness studies potentially deal with diminished internal study validity. One concern is confounding of outcome by extraneous factors, which is an important reason for investigating

predictors of treatment outcome in effectiveness research (Leichsenring, 2004). Finally, a limitation was the lack of a control group, as confounding factors were not measured.

This study also has several strengths. Analyses were done in a clinically relevant context, with a large sample of patients referred to a specialised eating disorder clinic. Since 80.3% of all participants who completed treatment complied with the request to complete the assessments, persistence of benefits of treatment could be assessed at 20 weeks follow up. These results can therefore be generalised to other specialised treatment centres. In addition, all therapists completed their web-centred CBT-E training, were intensively supervised and treatment integrity and protocol adherence was monitored. Since the recent acknowledgement of BED in the DSM V (APA, 2013), this is, as far as we know, the first study to report CBT-E effectiveness in adult patients diagnosed with BED compared to other eating disorders. Furthermore, additional analyses were performed to assess whether OSFED classification determined group categorization. In terms of feasibility, the present study shows that CBT-E can be delivered in everyday clinical practice in a specialised eating disorders centre.

In conclusion, CBT-E appeared a suitable eating disorder treatment for adults with a BMI between 17.6 and 39.9. Treatment benefits were maintained during 20 weeks follow up. While there were no significant differences in remission between BN, BED and their respective OSFED and OSFED with a restrictive food pattern, treatment completion was significantly lower in the BN group. The findings are consistent with a transdiagnostic treatment approach. The question for whom CBT-E works best requires further study, because the present data revealed only predictive value of pre-treatment severity of the eating disorder and no other predictors were found.

Key practice points

- (1) CBT-E is an effective treatment for patients suffering from an eating disorder with a BMI between 17.6-39.9
- (2) No subgroup of patients benefited differentially from CBT-E
- (3) Only severity of eating disorder pathology at start predicted treatment outcome
- (4) Drop-out of treatment was only predicted by the diagnosis of bulimia nervosa
- (5) Patients might also recover with a less intense form of treatment

Supplementary Table A

Remission rates of CBT-E for various eating disorder classifications

Diagnosis	Type of Remission	Time of Measurement	Remission Rates ¹	Author, year
Transdiagnostic model				
	EDE-Q	EOT	35-69.1%	Berg., et al, 2020 ; Byrne., et al, 2011; Dalle Grave., et al, 2015; Fairburn et al., 2015; Fairburn et al., 2009; Signorini., et al, 2018; Byrne., et al, 2017; Wade et al., 2016 ² ; Watson., et al, 2012
		20 weeks FU	58-65%	Fairburn et al., 2015; Fairburn et al., 2009; Signorini et al., 2018
		40 weeks FU	65-70%	Fairburn et al., 2015; Fairburn et al., 2009
	Full recovery	EOT	45%	Fairburn et al., 2015
		EOT	50%	Dalle Grave et al., 2015
		EOT	39.1%	Berg., et al, 2020
AN				
	EDE-Q	EOT	18-40%	Byrne et al., 2011; Calugi, El Ghoch, & Dalle Grave, 2017; Watson et al., 2012
	Full recovery	EOT	14.3-30%	Calugi et al., 2017; Wade et al., 2017
	BMI>18,5	EOT	31.2-36.4%	Byrne et al., 2011; Frostad et al., 2018
		One year FU	50-77.3%	Frostad et al., 2018
BN				
	EDE-Q	EOT	22.5-53%	Fairburn et al., 2009; Poulsen et al., 2014; Watson et al., 2012; Wonderlich et al., 2014
		60 weeks FU	50-69%	Fairburn et al., 2009; Fairburn et al., 2015., Wonderlich et al., 2014
BN and OSFED				
	EDE-Q	EOT	78%	Knott, Woodward, Hoefkens, & Limbert, 2015
BN and borderline personality disorder				
	EDE-Q	EOT	40-44%	Thompson-Brenner et al., 2016
OSFED				
	EDE-Q	EOT	27-54%	Fairburn et al., 2009; Watson et al., 2012
		60 weeks FU	46%	Fairburn et al., 2009

¹ EDE-Q < 1SD above community norm, no remission rates for BED specifically have been reported, ² group CBT-E

EOT end of treatment, *FU* follow-up
