Abstract

We have entered the era of the James Webb Space Telescope (JWST). We use the first JWST transmission spectrum of the hot Saturn-mass exoplanet, WASP-39 b, obtained with the NIRSpec instrument in the 3–5 μm range to investigate (a) what atmospheric constraints are possible with JWST-quality data in this spectral range, (b) requirements for atmospheric models used in retrievals, (c) effect of differences between data reduction pipelines on retrieved atmospheric properties, and (d) complementarity between JWST data in the 3–5 μm range and Hubble Space Telescope (HST) observations at shorter wavelengths. JWST spectra in the 3–5 μm range provide a promising avenue for chemical detections while encompassing a window in cloud opacity for several prominent aerosols. We confirm recent inferences of CO_2 , SO_2 , H_2O , and CO in WASP-39 b; report tentative evidence for H_2S ; and retrieve elemental abundances consistent with Saturn’s metallicity. We retrieve molecular abundances with ~ 0.3 – 0.6 dex precision with this relatively limited spectral range. When considering the 3–5 μm data alone, reported differences in spectra with different reduction pipelines can affect abundance estimates by up to ~ 1 dex and the detectability of less prominent species. Complementing with data at shorter wavelengths, e.g., with other JWST instruments or HST WFC3 (~ 0.8 – 1.7 μm), can significantly improve the accuracy and precision of the abundance estimates. The high data quality enables constraints on aerosol properties, including their composition, modal size, and extent, motivating their consideration in retrievals. Our results highlight the promise of JWST exoplanet spectroscopy, while underscoring the importance of robust data reduction and atmospheric retrieval approaches in the JWST era.

1. Introduction

The first observations with the James Webb Space Telescope (JWST) are now available, heralding the dawn of a new era in our understanding of exoplanetary atmospheres. With a virtually complete coverage of the near-mid-infrared, transmission spectroscopy with JWST enables simultaneous constraints on multiple chemical species and other physical properties in exoplanetary atmospheres (Beichman et al. 2014; Stevenson et al. 2016; Batalha & Line 2017; Bean et al. 2018; Kalirai 2018; Sarkar et al. 2020). The generational leap in our understanding of chemical and physical processes in exoplanets is already underway.

Exoplanet transmission spectroscopy with the Hubble Space Telescope (HST), along with ground-based observations with facilities like the Very Large Telescope (VLT), have over the past 20 years been a key driver of the field’s remarkable growth (Seager & Sasselov 2000; Charbonneau et al. 2002; Vidal-Madjar et al. 2003; Deming et al. 2013; Ehrenreich et al. 2015; Nikolov et al. 2016; Sing et al. 2016; Kreidberg 2018). Paired with theoretical developments in atmospheric modeling and retrievals, HST transmission spectra in the optical and near-infrared (NIR) have led to important constraints on the abundances of chemical species including H_2O , Na and K, as

well as the properties of clouds and hazes in several exoplanetary atmospheres (Madhusudhan & Seager 2009; Kreidberg et al. 2014; Madhusudhan et al. 2014; Barstow et al. 2017; Madhusudhan 2018; Wakeford et al. 2018; Pinhas et al. 2019; Welbanks et al. 2019). Most of these atmospheric detections were made for irradiated gas giants, whose relative rarity (Howard et al. 2010; Mayor et al. 2011; Wang et al. 2015; Fulton et al. 2021) is offset by their comparative observability. This is largely due to their extended, hydrogen-dominated atmospheres giving rise to large spectral signatures and hence high signal-to-noise observations.

Our goal in this work is to obtain a first glimpse into atmospheric properties of exoplanets that can be retrieved with JWST-quality transmission spectra. While observations with HST have been limited to wavelengths below 1.7 μm , JWST promises a substantial increase in both sensitivity and spectral range. In particular, the ~ 3 – 5 μm range accessible with the NIRSpec instrument (Ferruit et al. 2012) opens uncharted territory in chemical discovery space, as evidenced by recent inferences of CO_2 and SO_2 in the atmosphere of an exoplanet (Alderson et al. 2022; The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022; Rustamkulov et al. 2022). Here we assess atmospheric constraints that are possible with JWST transmission spectra in the ~ 3 – 5 μm range and modeling requirements for retrieval frameworks in the JWST era. We further investigate the sensitivity of retrievals to differences in spectra obtained using different data reduction pipelines as well as complementarity

with NIR spectra with the HST/WFC3 instrument (0.8–1.7 μm).

We focus on WASP-39 b, which is one of the first exoplanets whose transmission spectrum has been observed with JWST. The planet has a mass of $0.28 \pm 0.03 M_J$, a radius of $1.28 \pm 0.04 R_J$, and a zero-albedo equilibrium temperature of 1170 K (Faedi et al. 2011; Mancini et al. 2018). It orbits a G8-type host star with an intermediate brightness of $J = 10.7$ and $V = 12.1$ (Faedi et al. 2011). WASP-39 b is therefore an example of the immense diversity in the known exoplanet population. While its closest solar system analog by mass is Saturn ($M = 0.3 M_J$), it is significantly larger, with a radius greater than Jupiter’s and significantly more strongly irradiated than any solar system gas giant. The notably low gravity of WASP-39 b makes its atmosphere highly conducive to transmission spectroscopy observations and has already led to detections of H_2O , Na, and K with prior HST and ground-based facilities (Fischer et al. 2016; Nikolov et al. 2016; Sing et al. 2016; Tsiaras et al. 2018; Wakeford et al. 2018; Kirk et al. 2019; Pinhas et al. 2019; Welbanks et al. 2019; Kawashima & Min 2021). As a result, WASP-39 b is the target of choice for the JWST Early Release Science (ERS) program, which has already led to novel inferences of CO_2 and SO_2 in its atmosphere (Alderson et al. 2022; The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022; Rustamkulov et al. 2022).

We consider the JWST observations of WASP-39 b over the 3–5 μm range, obtained with the NIRSpec PRISM spectrograph (The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022). Beyond its high data quality, this spectral range is representative of the majority of observations JWST is set to make over Cycle 1. Specifically, most Cycle 1 observations are set to be made with the NIRSpec spectrograph using the G395 grating over a similar $\sim 3\text{--}5 \mu\text{m}$ range. As such, our work is also a feasibility study, with the present observations of WASP-39 b constituting a near-best-case scenario.

We also consider how minor variations in the JWST observations, particularly those arising from differences between reduction pipelines, can affect the retrieved atmospheric constraints. We do this by retrieving on two different reductions of the same observations, obtained with the Tiberius and Eureka pipelines, which have been reported to give slightly different results, particularly over the 3.6 μm Spitzer band (The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022).

Besides analyzing the JWST data alone, we also consider their complementarity with prior observations. For this work, we consider pairing the 3–5 μm JWST observations with those obtained previously with HST/WFC3 (0.8–1.7 μm), examining how this affects the precision and accuracy of atmospheric constraints. This pairing is particularly important, as several of the Cycle 1 targets have been or are set to be also observed with HST/WFC3. In doing so, we seek to assess the complementarity between JWST 3–5 μm observations and HST.

In what follows, we discuss the observations in Section 2 and our retrieval methodology in Section 3. The results of our investigation are presented in Section 4, followed by our summary and discussion in Section 5.

2. Prior and Current Observations

The atmosphere of WASP-39 b has been extensively probed in transmission spectroscopy from both ground and space. The

first space-based observations were carried out in 2013, using the HST/STIS G430L and G750L gratings (GO 12473, PI: D Sing; Fischer et al. 2016; Sing et al. 2016), covering the 0.29–1.0 μm wavelength range. Paired with photometric observations with Spitzer (90092, PI: J.-M. Désert), these observations were used to infer a cloud-free atmosphere, with prominent spectral features arising from Na and K. This is in agreement with conclusions drawn from ground-based VLT observations by Nikolov et al. (2016), spanning the 0.4–0.8 μm range using the Focal Reducer/Low Dispersion Spectrograph 2 (FORSS2; 096.C-0765, PI: N. Nikolov).

Further spectroscopic observations were carried out in the NIR using the HST Wide Field Camera 3 (WFC3) G102 and G141 grisms (GO 14169, PI: H. Wakeford; GO 14260, PI: D. Deming), which together cover a wavelength range of 0.8–1.7 μm . These observations revealed prominent H_2O absorption features. Combining the new HST/WFC3 observations with prior ones with VLT, HST/STIS, and Spitzer, Wakeford et al. (2018) report an enriched atmospheric metallicity constraint of $151^{+48}_{-46} \times$ solar using a retrieval framework assuming chemical equilibrium. The median value corresponds to log-mixing ratios of ~ -1.3 , ~ -3.6 , and ~ -4.8 for H_2O , Na, and K, respectively. By contrast, Tsiaras et al. (2018), using an alternative reduction of the same HST/WFC3 G141 observations, find a significantly lower H_2O log-mixing ratio of -5.94 ± 0.61 .

This disparity in the inferred atmospheric composition of WASP-39 b persisted through subsequent analyses. Retrievals carried out by Pinhas et al. (2019) using the WFC3 G141 observations reduced by Tsiaras et al. (2018) along with HST/STIS and Spitzer data found an H_2O log-mixing ratio corresponding to a subsolar metallicity, at $-4.07^{+0.72}_{-0.78}$, but Na and K log-mixing ratios corresponding to a supersolar metallicity, at $-3.86^{+1.31}_{-1.36}$ and $-4.22^{+1.25}_{-1.12}$. Kirk et al. (2019) presented a combined transmission spectrum consisting of the HST/WFC3 observations presented by Wakeford et al. (2018) and Spitzer photometry in the NIR, while combining HST/STIS and VLT observations with new observations using the William Herschel Telescope in the optical. Using a retrieval framework assuming equilibrium chemistry, they obtain an atmospheric metallicity constraint of $282^{+65}_{-58} \times$ solar, at its median corresponding to H_2O , Na, and K log-mixing ratios of -1.0 , -3.3 , and -4.5 , respectively. Using this same combined data set, Welbanks et al. (2019) find that composition constraints are dependent on the choice of prior, obtaining log-mixing ratio estimates of $-0.65^{+0.14}_{-1.83}$, $-3.62^{+1.14}_{-2.69}$, and $-5.62^{+2.30}_{-2.05}$ for H_2O , Na, and K with their canonical retrieval, and $-2.43^{+0.27}_{-0.24}$, $-6.17^{+0.50}_{-0.51}$, and $-7.24^{+0.71}_{-1.06}$ for a more constrained prior. More recently, Kawashima & Min (2021), analyzing the combined HST/STIS, WFC3, and Spitzer observations presented by Sing et al. (2016), Fischer et al. (2016), and Wakeford et al. (2018), constrain an atmospheric metallicity consistent with solar to within 1σ when considering disequilibrium chemistry. They also report a moderately supersolar metallicity constraint when equilibrium chemistry is assumed, corresponding to an H_2O log-mixing ratio of ~ -2.7 .

The JWST observations of WASP-39 b used in the present study have been obtained with the NIRSpec PRISM (Ferruit et al. 2012; Birkmann et al. 2014) over a single transit in 2022 July as part of the JWST Early Release Science (ERS; The JWST Transiting Exoplanet Community Early Release Science

Figure 1. A transmission spectrum of WASP-39 b. The circles with error bars show the JWST NIRSpec PRISM spectrum in the 3–5 μm range reduced with the Tiberius pipeline (The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022) along with prior HST/WFC3 observations in the 0.8–1.7 μm range (Wakeford et al. 2018). The solid curve in brown shows our retrieved best-fit spectrum, and the same spectrum but without opacity contributions from aerosols is shown in blue for reference (see Section 4.2.1). The heights of the prominent spectral features in the JWST and HST bands in terms of a characteristic atmospheric scale height are denoted by arrows; a nominal slant photospheric temperature of 800 K is assumed motivated by the retrieved constraints. The contributions of individual molecules are shown in Figure 6 in the Appendix.

Team et al. 2022). Spanning a subset of the full NIRSpec PRISM $\sim 0.6\text{--}5\ \mu\text{m}$ range, the new data show absorption peaks that are significantly larger in size than those observed previously in the HST/WFC3 bandpass, corresponding to 6–8 versus 2–3 atmospheric scale heights. Several reductions of the same observations were presented, which are reported to be largely comparable but with small deviations, especially in the 3–4 μm range. For the sake of robustness, we consider two reductions, based on their level of agreement over the Spitzer 3.6 μm bandpass, in order to assess the effect different reduction pipelines may have on the retrieved atmospheric properties. Specifically, we use the data obtained using the Eureka and Tiberius pipelines. Both the Eureka and Tiberius pipelines give rise to observations that, when binned to the Spitzer 3.6 μm bandpass, are at a higher transit depth than that observed by Spitzer itself. The Tiberius pipeline value is consistent with the Spitzer point to within 1σ , while the Eureka value lies at $\sim 2\sigma$ of the Spitzer point and between those of the tshirt and FIREFLY pipelines. The 3–5 μm JWST data obtained with the Tiberius pipeline that are used in the present study are shown in Figure 1, along with prior observations with HST/WFC3.

3. Methods

We retrieve the atmospheric properties of WASP-39 b from the spectroscopic observations described in Section 2 using a variant of the AURA retrieval framework (Pinhas et al. 2018). The forward model computes radiative transfer in a plane-parallel atmosphere in transmission geometry. The model assumes hydrostatic equilibrium and local thermodynamic equilibrium in a H_2 -rich atmosphere. The pressure–temperature (P-T) profile and uniformly distributed volume mixing ratios of the chemical absorbers are free parameters in the model. In this work, we additionally retrieve the properties of Mie-scattering aerosols, as discussed in this section. We also consider the conventional parametric cloud/haze prescription in AURA, for reference, as well as the effect of stellar heterogeneities. The parametric atmospheric model is coupled to a Bayesian inference and parametric estimation routine based on the Nested Sampling algorithm,

implemented via the PYMULTINEST package (Feroz et al. 2009; Buchner et al. 2014; Feroz et al. 2019).

In order to consider the spectral contributions of aerosols the model includes extinction from Mie-scattering particles in the planetary atmosphere. Using the approach in Pinhas & Madhusudhan (2017) we explore a range of possible condensate species that can be prevalent in irradiated giant exoplanets, e.g., MgSiO_3 , Na_2S , MnS , ZnS , SiO_2 , Al_2O_3 , FeO , Fe_2O_3 , TiO_2 , NaCl , and Mg_2SiO_4 , based on data from Wakeford & Sing (2015) and Pinhas & Madhusudhan (2017). The extinction cross sections are computed following Mie theory (Bohren et al. 1983). We assume a modified gamma distribution for the aerosol particle sizes (Deirmendjian 1969), with the modal particle size, r_c , of the distribution, being a free parameter in the model. We additionally consider the vertical extent of the aerosol layer, described by the relative scale height of the aerosols, $h_c = \frac{H_c}{H}$, where H_c is the aerosol scale height and H is the atmospheric scale height. h_c is another free parameter in the model with values ranging from 0 to 1. An h_c value of 1 implies that aerosols have a constant mixing ratio with altitude, while a value of 0 corresponds to no aerosols being present in the observable atmosphere. We incorporate this in our model as an exponential decrease in the aerosol mixing ratio with altitude:

$$X_i(z) = X_{i,0} \exp\left[-\frac{(n-1)z}{H(z)}\right], \quad (1)$$

where X_i denotes the mixing ratio of the i^{th} aerosol species, $H(z)$ is the local atmospheric scale height $\frac{k_B T}{\mu g}$ at an altitude z , and $n = \frac{1}{h_c}$. Our model also accounts for an inhomogeneous coverage of the terminator atmosphere by aerosols, whose coverage fraction, f_c , is a third free parameter.

Our aerosol model can include an arbitrary number of aerosol species. The mixing ratio of each of the aerosol species is a separate free parameter. For the retrievals we consider in this work, the modal particle size, vertical extent, and fractional coverage parameters are universal, applying to all aerosol species in the model.

In light of the JWST observations probing a novel part of the spectrum and the high precision of observations, we carry out a

Table 1
Retrieved Atmospheric Parameters for WASP-39 b

Case	$\log(X_{\text{H}_2\text{O}})$	$\log(X_{\text{CO}_2})$	$\log(X_{\text{SO}_2})$	$\log(X_{\text{CO}})$	$\log(X_{\text{H}_2\text{S}})$	T_0/K
Canonical Retrieval Model

Note. The table shows the retrieved log-mixing ratios of molecules with notable detection significances along with the temperature at the top of the model atmosphere. The top four rows show the retrievals using our canonical model, with the top two obtained with JWST NIRSpec 3–5 μm data alone and the remaining two with a combination of JWST and HST data. We consider JWST data reported using two pipelines, Tiberius and Eureka, as discussed in Section 4. The bottom four rows show constraints on the JWST+HST data obtained with two other retrieval considerations: (a) replacing the Mie-scattering aerosols with a conventional parametric cloud/haze prescription, and (b) including stellar heterogeneities, as described in Section 3.

staged retrieval approach. We begin by considering a maximal set of gaseous and Mie-scattering aerosol species. This maximal model considers opacity contributions from a large number of gaseous chemical species. It also includes Mie scattering arising from inhomogeneous coverage of the terminator atmosphere by aerosols of MgSiO_3 , Na_2S , MnS , ZnS , SiO_2 , Al_2O_3 , FeO , Fe_2O_3 , TiO_2 , NaCl , and Mg_2SiO_4 (Wakeford & Sing 2015; Pinhas & Madhusudhan 2017).

We then consider a reduced canonical set of parameters, based on initial indications by our maximal retrieval and chemical expectations, which we use for all retrieval cases presented in this work. The final set of gaseous chemical species included in the present canonical model comprises H_2O , CO , CO_2 , H_2S , SO_2 , CH_4 , NH_3 , HCN , and C_2H_2 . We additionally include opacity contributions arising from H_2 – H_2 and H_2 – He collision-induced absorption (Richard et al. 2012), as well as ZnS (Querry 1987) and MgSiO_3 (Dorschner et al. 1995) aerosols. Our choice for these two aerosol species is driven by both thermochemical expectations for the condensates based on the terminator temperature (Morley et al. 2013) and indicative constraints obtained with our maximal model retrievals. The absorption cross sections for the gaseous species are derived following Gandhi & Madhusudhan (2017), using line lists of H_2O , CO , and CO_2 from Rothman et al. (2010) and Li et al. (2015), CH_4 from Yurchenko & Tennyson (2014), NH_3 from Yurchenko et al. (2011), HCN from Harris et al. (2006) and Barber et al. (2014), C_2H_2 from Chubb et al. (2020), SO_2 from Underwood et al. (2016), and H_2S from Azzam et al. (2016) and Chubb et al. (2018).

Our canonical atmospheric model has a total of 21 free parameters. The first nine correspond to the individual log-mixing ratios of the gaseous chemical species listed above. Another two free parameters describe the log-mixing ratios of ZnS MgSiO_3 aerosols and another three describe their fractional coverage, modal particle size, and vertical extent, as described above. The terminator temperature profile is modeled by six parameters using the parameterization of Madhusudhan & Seager (2009). The last free parameter for our canonical model is the planet radius, R_p , defined at a nominal reference pressure of 0.1 bar. For retrievals on combined JWST

and HST/WFC3 observations, we additionally retrieved for a linear offset between the two data sets.

We use log-uniform priors between 10^{-12} and $10^{-0.3}$ for the mixing ratios of gaseous species, and between 10^{-30} and 10^{-6} for the mixing ratios of MgSiO_3 and ZnS aerosols. We set the prior for the modal particle size, r_c , to a log-uniform distribution ranging between 1 nm and 1 μm , and both the f_c and h_c priors are uniform between 0 and 1. The prior for the temperature at the top of the atmosphere, T_0 , is also uniformly distributed between 300 and 1600 K.

For completeness, we also explore retrievals including the effects of stellar heterogeneities as well as a more traditional parametric approach to model clouds/hazes, instead of Mie scattering by aerosols, as pursued by default in AURA. For the parametric clouds/hazes, we use a four-parameter combination of inhomogeneous gray opacity clouds and modified Rayleigh-like hazes (MacDonald & Madhusudhan 2017; Pinhas et al. 2018). We incorporate stellar heterogeneities in the model following Rackham et al. (2017) as described in Pinhas et al. (2018). This model involves three free parameters, describing the fractional surface coverage of heterogeneities, their overall effective temperature, and the temperature of the pristine photosphere.

4. Results

We now proceed to investigate the performance of atmospheric retrievals on a JWST spectrum of WASP-39 b. We first consider the JWST/NIRSpec PRISM observations on their own, examining the constraints such observations can lead to. We also assess how the retrieved atmospheric constraints vary due to minor differences between reduction pipelines, by considering JWST observations reduced by both Tiberius and Eureka. We then present our findings from joint retrievals on both the JWST observations over the 3–5 μm range and prior HST/WFC3 data. In doing so we establish the complementarity between JWST and HST/WFC3. We once again carry this out for data obtained with both the Tiberius and Eureka reduction pipelines, examining the differences between the resulting atmospheric constraints and how they vary with

differences in our retrieved atmospheric model. Our retrieved constraints are summarized in Table 1.

4.1. Retrievals with JWST Data

We first focus on the recently released JWST observations of WASP-39 b. As discussed in Section 3, we analyze the observations with a staged retrieval approach. We begin by considering a maximal set of chemical species, including gases and Mie-scattering aerosols. We then consider a reduced set of chemical absorbers, based on physical plausibility and their initial constraints obtained by our maximal retrieval. Our reduced set of chemical species comprising our canonical model consists of H₂O, CO, CH₄, HCN, H₂S, and SO₂, as well as ZnS and MgSiO₃ aerosols.⁵

We consider data obtained with the Tiberius and Eureka pipelines presented by The JWST Transiting Exoplanet Community Early Release Science Team et al. (2022), which produce somewhat different transit depths when binned over the Spitzer 3.6 μ m photometric band. Specifically, the Tiberius pipeline produces data that are the closest to the Spitzer 3.6 μ m transit depth measurement, with all other pipelines including Eureka that yield transit depths that are more than 1 σ higher than the Spitzer value.

The retrieved spectral fit to the JWST observations with our canonical model is shown in Figure 2. The observations display a highly prominent absorption peak at 4.3 μ m that has been previously attributed to CO₂ (The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022), as well as a smaller absorption feature at 4.0 μ m. Moreover, the spectrum trends upward at shorter wavelengths. For both reduction pipelines, our retrievals produce good fits to the data.

4.1.1. Tiberius Reduction

We begin by considering the data obtained via the Tiberius reduction pipeline. As shown in Figure 2, our retrieval obtains a good fit to the two significant absorption features at 4.0 and 4.3 μ m, as well as the trend of increasing transit depth toward lower wavelengths. Moreover, the retrieval also fits smaller features within that trend. We confirm that the larger peak at 4.3 μ m is due to CO₂, and the smaller peak at 4.0 μ m is due to SO₂, as reported previously (The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022; Rustamkulov et al. 2022).

Our retrievals obtain constraints for the log-mixing ratios of CO₂, SO₂, H₂O, H₂S, and CO. Driven by the very prominent CO₂ absorption peak at 4.3 μ m, we constrain the log-mixing ratio of CO₂ to $-6.28_{-0.31}^{+0.38}$. Additionally, our retrieval attributes the smaller absorption peak seen at 4.0 μ m to SO₂, constraining its log-mixing ratio to $-7.01_{-0.20}^{+0.23}$. CO is invoked to explain the data redward of the CO₂ feature, with a log-mixing ratio of $-4.25_{-0.35}^{+0.39}$. Additionally, H₂O and H₂S are constrained to log-mixing ratios of $-4.85_{-0.35}^{+0.38}$ and $-5.32_{-0.42}^{+0.36}$, respectively, and are used to fit the spectrum below 4.0 μ m. The posterior distributions retrieved for each of these molecules are shown in Figure 3.

In addition to the above mixing ratio constraints, our retrieval obtains a P-T profile that is consistent with an isotherm to within 1 σ , constraining T_0 , the temperature at the top of the model atmosphere to 862_{-63}^{+64} K. Additionally, this

retrieval does not obtain any constraints for the properties of Mie-scattering aerosols. The posterior distributions for the log-mixing ratios of MgSiO₃ and ZnS are largely unconstrained, with that of MgSiO₃ displaying a somewhat prominent peak at ~ -10 . The posterior distributions for the modal particle size, fractional terminator coverage, and vertical extent are also unconstrained.

We carry out additional retrievals to assess the detection significance for each of the constrained molecules presented above. We do this by performing a Bayesian model comparison between our canonical retrieval model and one without the molecule in question (Pinhas et al. 2018). We find that both SO₂ and, particularly, CO₂ are confidently detected. In the case of CO₂, the model including it is preferred at a $\sim 16\sigma$ level, while the inclusion of SO₂ in the model is favored at a $\sim 4\sigma$ level. This is consistent with the fact that both molecules present significant absorption features in the observed wavelength range, and their exclusion therefore significantly deteriorates the achievable fit. All other molecules are retrieved with a lower detection significance. We find that H₂O, which was previously detected with HST/WFC3 observations, and CO, which was undetected before the advent of JWST, are both preferred at a $\sim 3\sigma$ level. Additionally, H₂S is marginally preferred at a $\sim 2\sigma$ level.

We therefore find that while the detection significance of each molecule varies significantly, they are all retrieved with roughly similar precision, e.g., both CO₂ and H₂S are constrained with a precision of 0.4 dex, despite CO₂ having an extremely high detection significance while the H₂S is only marginally preferred. As such, the precision with which the abundance of a chemical species is estimated is not necessarily indicative of how robustly it is detected.

4.1.2. Eureka Reduction

We now consider retrievals carried out on the 3–5 μ m JWST data obtained with the Eureka reduction pipeline. This data set is more deviant from the Spitzer 3.6 μ m channel data point than that from the Tiberius pipeline, with the resulting averaged transit depth lying $\sim 2\sigma$ higher than the Spitzer point. It is representative of multiple data reductions presented by The JWST Transiting Exoplanet Community Early Release Science Team et al. (2022).

With this data set, our retrievals once again provide abundance constraints for several molecules. These include CO₂, at a log-mixing ratio of $-5.11_{-0.54}^{+0.63}$, as well as SO₂ at $-6.40_{-0.35}^{+0.39}$, which the retrieval invokes to explain the feature at 4.0 μ m, similarly to our findings with the Tiberius reduction data. The retrieval also constrains the mixing ratios of H₂O, CO, and H₂S to $-3.29_{-0.56}^{+0.59}$, $-4.17_{-0.61}^{+0.61}$, and $-4.11_{-0.46}^{+0.49}$, respectively. The retrieval additionally obtains posterior distributions for CH₄ and HCN that are notably peaked at log-mixing ratio values of ~ -7 and ~ -6 , respectively, but have significant probability density extending to the lower end of the prior range. As such neither constitutes a precise or robust constraint.

The retrieval does not obtain any constraints for the properties of our included ZnS and MgSiO₃ aerosols. The mixing ratios for both aerosol species remain unconstrained, as were the posteriors for the fractional cloud coverage, particle size, and vertical extent. Higher aerosol mixing ratios coincide with smaller particle sizes, which together result in negligible spectral contributions. We also once again retrieve a P-T profile that is consistent with an isotherm to within 1 σ . Our retrieval

⁵ During the preparation of this work, we learned about the independent inference of SO₂ using the same data (Rustamkulov et al. 2022).

Figure 2. Retrieved spectral fits obtained for two of the retrievals considered in this work, using our canonical model described in Section 3. The top panel shows the retrieved spectral fit for JWST NIRSpec PRISM 3–5 μm observations reduced with the Tiberius pipeline (data shown in black error bars with yellow circles). Also shown are the same observations reduced with the Eureka pipeline (in green). The bottom two panels show different wavelength regions of the retrieved spectral fit to the combination of HST/WFC3 observations (0.8–1.7 μm) and JWST/NIRSpec PRISM observations reduced with Tiberius; see Section 2. In all three panels, the darkest orange line denotes the median retrieved spectrum while the two lighter orange regions denote the corresponding 1 σ and 2 σ contours.

constrains T_0 , the temperature at the top of the atmosphere, to 738_{-55}^{+54} K.

As before, we perform Bayesian model comparisons to assess the degree of model preference for including each molecule with abundance constraints. We find a very significant model preference toward the inclusion of CO_2 at $\gtrsim 20\sigma$, while SO_2 and H_2O are preferred at a $\sim 4\sigma$ level. The detection significances for CO and H_2S are once again not as high as those obtained for CO_2 and SO_2 , both of which are preferred at a $\sim 3\sigma$ level.

The inclusion of CO in the model is favored at a $\sim 3\sigma$ level. Finally, the inclusion of H_2S is preferred at a $\sim 4\sigma$ level. As with our prior retrieval on data from the Tiberius pipeline, we find that the precision with which the mixing ratio of each species is constrained is not indicative of how confidently it is detected.

4.1.3. Comparison of Retrieved Constraints

Both reduction pipelines lead to mixing ratio constraints with precisions below 1 dex. Additionally, both lead to extremely confident detection significances for CO_2 as well as a less

confident but still robust detection of SO_2 . They also both result in moderate model preferences in favor of H_2O and CO .

Despite the above, we find significant differences in atmospheric parameters retrieved with the two data sets. Most notably, despite their precision, the retrieved abundance constraints for CO_2 , SO_2 , H_2O , and CO from the two data sets are not consistent to within 1σ , in some cases differing by 1 dex or more. This indicates that each data set leads retrievals to a different spectral baseline. As a result, retrievals then invoke different amplitudes of spectral features in order to explain the data. Another significant difference is in the detection significance of H_2S , with Eureka leading to a relatively robust detection of 4σ while Tiberius leads to only a tentative indication of its presence, with a 2σ detection significance. We additionally find other pipeline-specific features, in the form of peaked, but largely unconstrained posterior distributions for HCN and CH_4 obtained with the Eureka pipeline data but not with the Tiberius data.

We also find differences between the retrieved temperature profiles. While both retrievals obtain P-T profiles that are consistent with an isotherm, they lie more than 2σ away from

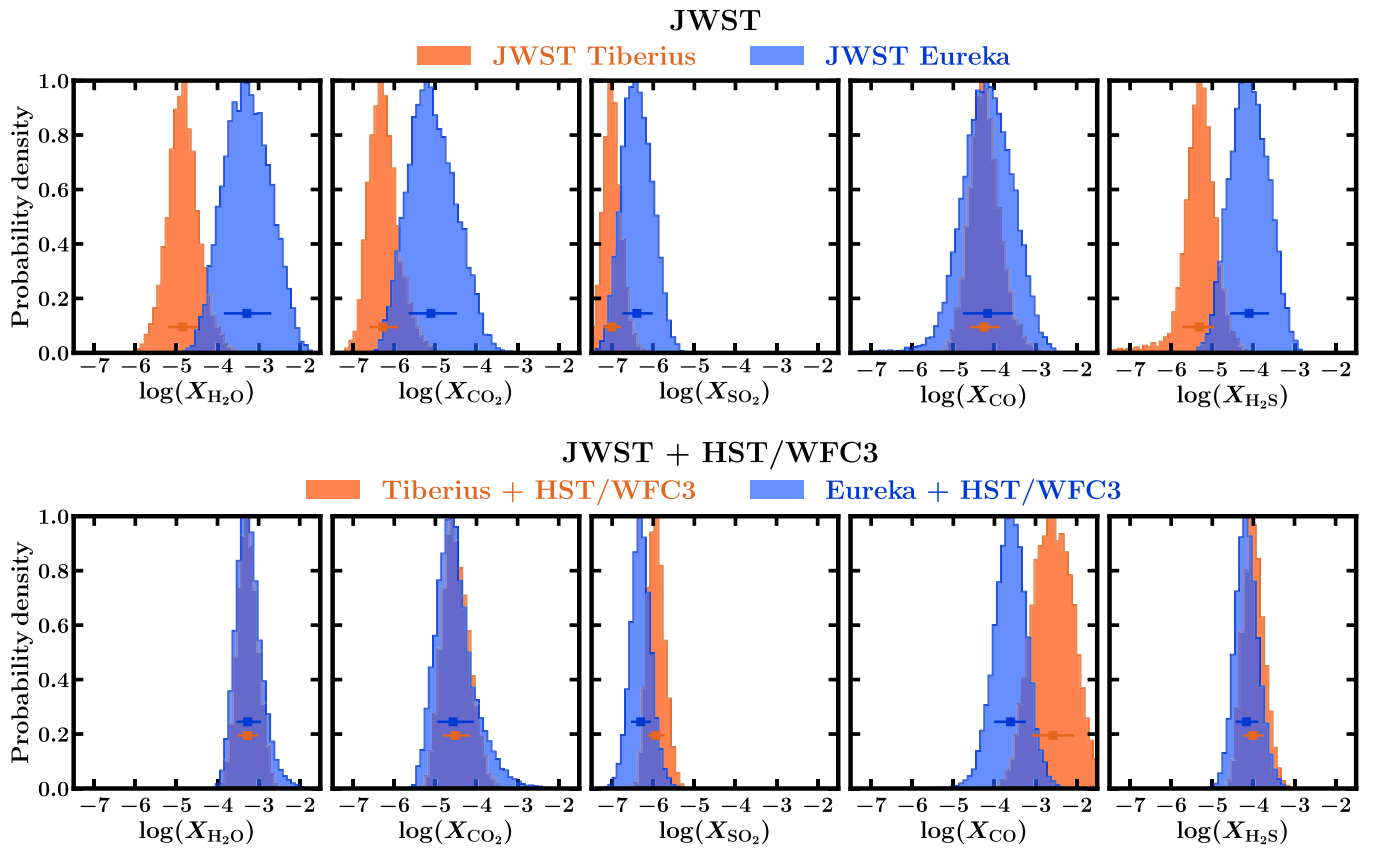

Figure 3. Posterior distributions of retrieved molecular abundances. Top: posteriors obtained with JWST NIRSpec PRISM 3–5 μm data reduced by the Tiberius and Eureka pipelines (The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022). Bottom: posteriors with the same two JWST spectra combined with HST/WFC3 data (Wakeford et al. 2018). From left to right, the panels show the posteriors for log-mixing ratios of H₂O, CO₂, SO₂, CO, and H₂S. Horizontal error bars denote the retrieved median and 1σ interval for the posterior of corresponding color.

each other. This is likely another consequence of the two data sets leading retrievals to different spectral baselines.

Thanks to the extreme precision of the JWST observations, we therefore find that pipeline-specific features can lead to significant differences in retrieved quantities. As such, we find that while both retrievals lead to molecular detections of key species, they can lead to significantly different mixing ratio estimates. As such, the significance with which a chemical species is detected may not always indicate an accurate abundance estimate, when considering spectra in the $\sim 3\text{--}5\ \mu\text{m}$ range alone.

4.2. Retrievals on Combined JWST and HST Observations

We now examine how atmospheric constraints retrieved from JWST observations in the $\sim 3\text{--}5\ \mu\text{m}$ are affected when we additionally include observations at shorter wavelengths obtained with HST/WFC3. This allows us to assess the complementarity of JWST observations over the 3–5 μm range, which form a substantial part of JWST Cycle 1 programs, with HST spectra at shorter wavelengths (0.8–1.7 μm). As before, we consider JWST spectra obtained with the Tiberius and Eureka pipelines and in both cases combine them with HST/WFC3 G102 and G141 observations in the $\sim 0.8\text{--}1.7\ \mu\text{m}$ range presented by Wakeford et al. (2018). We retrieve with the same canonical atmospheric model as in prior sections, which is described in detail in Section 3. As noted there, we additionally retrieve for a vertical linear offset between the JWST and HST/WFC3 data sets.

4.2.1. Tiberius Reduction and HST/WFC3

We first consider adding HST/WFC3 observations to $\sim 3\text{--}5\ \mu\text{m}$ JWST/NIRSpec PRISM data reduced with the Tiberius pipeline. Our retrieval once again achieves a good fit to the JWST/NIRSpec observations, while also finding a good fit to the HST/WFC3 data. The best-fit spectrum, along with the corresponding scale heights of different features, is shown in Figure 1. The individual molecular opacity contributions to the best-fit spectrum are shown in Figure 6 in the Appendix. Additionally, the retrieved median spectral fit and corresponding 1σ and 2σ contours are shown in Figure 2. The retrieval invokes H₂O to explain the HST/WFC3 data as expected, while the JWST observations are explained with CO₂, SO₂, H₂S, and CO. Notably, the size of the CO₂ feature is significantly larger (~ 8 scale heights) than that of H₂O in the HST/WFC3 band ($\sim 2\text{--}3$ scale heights).

The retrieved atmospheric constraints from this combined data set retrieval are notably different from those obtained from the JWST data alone, with the increased spectral coverage at shorter wavelengths leading the retrieval to better constrain the spectral baseline. Specifically, the retrieved log-mixing ratios for CO₂ and SO₂ are now $-4.52^{+0.36}_{-0.30}$ and $-5.94^{+0.22}_{-0.19}$, while that of H₂O is constrained to $-3.27^{+0.26}_{-0.24}$. Additionally, CO and H₂S are constrained to log-mixing ratios of $-2.58^{+0.51}_{-0.50}$ and $-4.01^{+0.27}_{-0.24}$. Compared to the estimates obtained from our retrieval on Tiberius-derived data alone, the present constraints are all higher by ~ 1 dex or more. The complete posterior distribution is shown in Figure 4.

Figure 4. Full posterior distribution from the retrieval using the JWST/NIRSpec PRISM 3–5 μm spectrum, reduced with the Tiberius pipeline, combined with HST/WFC3 data (0.8–1.7 μm). The model parameters correspond to the canonical atmospheric model described in Section 3. Horizontal error bars denote the median and 1σ interval for each retrieved parameter. Also shown is the retrieved P-T profile, with the black line denoting the median retrieved profile, while darker and lighter orange contours indicate the 1σ and 2σ intervals.

The increase in wavelength coverage also allows our retrieval to constrain the broad wavelength contributions from Mie-scattering MgSiO_3 aerosols. Specifically, we obtain a log-mixing ratio constraint of $-6.99^{+0.55}_{-0.65}$ for MgSiO_3 particles, with a modal particle size of $\log(r_c/\mu\text{m}) = -2.71^{+0.20}_{-0.17}$. These particles are found to be extended up to high altitudes, with a relative scale height, h_c , of $0.85^{+0.08}_{-0.9}$ and occupying roughly half of the terminator atmosphere, with a coverage fraction constrained to $51^{+7}_{-7}\%$. Meanwhile, we also find an upper limit

for the mixing ratio of ZnS particles of -9.81 at 99% confidence. This indicates that the data are best fit by spectral features specific to MgSiO_3 .

The retrieved spectral contributions from the MgSiO_3 aerosol particles are such that there is significant opacity contributions over the HST/WFC3 wavelength range, while the 3–5 μm range covered by the NIRSpec PRISM observations lies mostly within an opacity window. As such, it is likely that retrievals on these JWST observations alone are unable to

distinguish between a cloud-free case and one with most of the observations lying within an opacity window of a partially cloudy atmosphere.

Our retrieval also finds a P-T profile that is not consistent with an isotherm to within 1σ , as shown in Figure 4. Specifically, our retrieval constrains T_0 , the temperature at the top of the atmosphere to 757^{+40}_{-43} K. The constrained P-T profile then increases in temperature at higher pressures, with the median profile reaching a temperature of ~ 900 K at a pressure of 1 bar.

We once again carry out a Bayesian model comparison to assess the detection significance for each molecule. We find that the inclusion of CO_2 is again very strongly preferred, at a $\sim 20\sigma$ level. H_2O is now also strongly preferred, at a $\sim 13\sigma$ level, thanks to the addition of HST/WFC3 observations that encompass strong H_2O absorption features. SO_2 meanwhile is preferred at a $\sim 4\sigma$ level, while now the inclusion of H_2S is also preferred at a $\sim 4\sigma$ level. Finally, the inclusion of CO is preferred at $\sim 3\sigma$ level. H_2S in particular is now more strongly preferred than when retrieving on JWST data alone in Section 4.1.1.

We therefore find that the inclusion of HST/WFC3 observations are highly informative to retrievals on JWST observations in the $\sim 3\text{--}5\ \mu\text{m}$ range. This is evident in the significantly higher retrieved abundance constraints relative to those obtained with the same JWST data alone in Section 4.1.1, as well as their increased precision and detection significances. Moreover, we find that combined HST/WFC3 and JWST observations over the $3\text{--}5\ \mu\text{m}$ range can, in principle, lead to constraints for the physical properties of atmospheric aerosols, as well as the terminator's temperature structure.

4.2.2. Eureka Reduction and HST/WFC3

We now consider pairing the JWST/NIRSpec $3\text{--}5\ \mu\text{m}$ data obtained with the Eureka pipeline with HST/WFC3 G141 and G102 observations. Unlike the retrievals on data from the Tiberius pipeline described above, we find that combining HST/WFC3 data with observations reduced with Eureka does not lead to significant changes in the retrieved atmospheric properties. Specifically, our retrieval constrains the log-mixing ratio of CO_2 to $-4.57^{+0.51}_{-0.38}$, SO_2 to $-6.31^{+0.25}_{-0.24}$, H_2O to $-3.28^{+0.33}_{-0.27}$, CO to $-3.61^{+0.37}_{-0.40}$, and H_2S to $-4.17^{+0.29}_{-0.26}$. These constraints are generally more precise than those obtained with the corresponding JWST/NIRSpec data alone.

We find tentative indications of spectral contributions from Mie-scattering aerosols using this data set. Specifically, we find an upper limit for the mixing ratio of ZnS of -6.65 at 99% confidence, which corresponds to significant spectral contributions. The same is true for the constraints obtained for $\log(r_c/\mu\text{m})$, f_c , and H_c , which have 99% confidence upper limits of 0.96, -6.15 , and 0.97. This indicates that the data do not preclude significant spectral contributions from aerosols. Meanwhile, the posterior for the mixing ratio of MgSiO_3 aerosols is unconstrained.

The retrieval finds an atmospheric P-T profile that is consistent with an isotherm to within 1σ . Specifically, it constrains the T_0 , the temperature at the top of the atmosphere to 666^{+53}_{-72} K. Notably, this temperature is more than 1σ away from that obtained with only JWST/NIRSpec data.

As with other retrievals, we find that the inclusion of CO_2 in our retrieved atmospheric model is very strongly preferred, with a detection significance of $\sim 25\sigma$. H_2O is also preferred at

a lower but still highly confident $\sim 12\sigma$ level. Meanwhile, SO_2 , H_2S , and CO are all preferred at a $\sim 3\sigma$ level.

We therefore find that the addition of HST/WFC3 observations to the Eureka pipeline data once again affects the retrieved atmospheric properties. In addition to improving the precision of all abundance constraints, including those with no features in the HST/WFC3 band, it also leads to different results for aerosol parameters.

4.2.3. Comparison of Retrieved Constraints

We find that the retrieved mixing ratio values for H_2O , CO_2 , SO_2 , and H_2S all now agree to within 1σ between the two JWST pipelines. This is a notable difference with our prior retrievals on JWST data alone, which differed by 1 dex or more. On combining HST/WFC3 data with JWST data from the Tiberius pipeline, we find that there is a significant change in the retrieved abundance constraints, in some cases increasing by more than 1 dex relative to those obtained from JWST observations alone. Meanwhile, adding HST/WFC3 observations to data from the Eureka pipeline does not result in as significant a shift in retrieved mixing ratios.

Despite the general agreement between the retrieved mixing ratio values, differences still persist between the two JWST data sets. Most notably, the retrieved mixing ratios of CO differ by more than 1σ . Such pipeline-specific constraints persist when we consider an expanded retrieval model, such as one including KOH and NaOH, which may be present based on prior Na and K constraints. In this case, we find that the HST/WFC3 + Eureka data set leads to a preference for KOH rather than H_2S , while retrieving on HST/WFC3 + Tiberius still leads to a preference for H_2S over KOH.

Second, we find different reduction pipelines also lead to different constraints for aerosols present in the atmosphere. In the case of our retrievals on the HST/WFC3 + Tiberius data set, we obtain precise constraints on submicron MgSiO_3 aerosols covering roughly half the terminator atmosphere with an effectively full vertical atmospheric extent. The retrieval also specifically invoked MgSiO_3 as opposed to ZnS, which is also a part of our canonical model. Meanwhile, the retrieval on HST/WFC3 + Eureka data instead leads to only tentative constraints for ZnS aerosols and none for MgSiO_3 .

Finally, we also find different retrieved temperature profiles. Retrieving on HST/WFC3 + Tiberius data, we find a nonisothermal P-T profile, which may also be consistent with that obtained with Tiberius pipeline data alone, depending on the specific altitude probed by the retrieval. Meanwhile, the HST/WFC3 + Eureka data set leads to a P-T profile that is consistent with an isotherm. It is also inconsistent with the temperature obtained with Eureka pipeline data alone, as well as the temperature obtained with HST/WFC3 + Tiberius. The temperature constraint is relevant for interpreting the retrieved atmospheric composition and understanding the physical and chemical processes giving rise to it. We also conclude that while precise transmission spectra over a wide wavelength range can in principle lead to constraints for the terminator's temperature structure, such constraints are sensitive to minor variations in the data, such as those introduced by differences in reduction pipelines.

We also consider how our findings are affected by changes to our model, described in Section 3, the results of which are summarized in Table 1. On including the effects of stellar heterogeneities in our model, we find that our retrieved

abundance constraints are consistent with those obtained with our canonical model. We also consider the impact of using a parametric cloud/haze prescription rather than physically motivated Mie-scattering aerosols. In this case, we find that our retrieved abundances are different by up to ~ 0.5 dex, underscoring the need for a physically motivated aerosol model in order to obtain accurate abundance constraints in the JWST era.

5. Summary and Discussion

We use the first JWST observations of an exoplanet transmission spectrum in the $3\text{--}5\ \mu\text{m}$ range to obtain early insights into atmospheric retrievals that are possible in the JWST era. This spectral range is particularly important to investigate, considering the large allocation of JWST time in Cycle 1 for exoplanet spectroscopy using NIRSpec observations in the $\sim 3\text{--}5\ \mu\text{m}$ range. We focus on the JWST NIRSpec PRISM observations of the hot Saturn WASP-39b, observed as part of the JWST ERS program (The JWST Transiting Exoplanet Community Early Release Science Team et al. 2022), arguably one of the most promising exoplanets for transmission spectroscopy. Our goal is to investigate (a) the nature of atmospheric constraints that are possible with high-precision JWST data in the $\sim 3\text{--}5\ \mu\text{m}$ range, (b) modeling requirements for atmospheric retrievals with such data, (c) how sensitive the retrieved atmospheric properties are to differences in spectra from different reduction pipelines, and (d) how such data may be complemented with observations at shorter wavelengths.

5.1. Key Lessons

We identify the following key lessons for atmospheric retrievals of transiting exoplanets using JWST transmission spectra, particularly in the $3\text{--}5\ \mu\text{m}$ range.

1. The $\sim 3\text{--}5\ \mu\text{m}$ range provides an important avenue for molecular detections, as it encompasses windows in extinction cross section for several aerosols. Consequently, molecular opacity within this range can give rise to highly prominent spectral features. JWST observations over the $\sim 3\text{--}5\ \mu\text{m}$ may therefore lead to confident molecular detections even for potentially cloudy atmospheres with low-amplitude ($\lesssim 2\text{--}3$ scale height) spectral features in the HST/WFC3 band ($\sim 0.8\text{--}1.7\ \mu\text{m}$; e.g., Stevenson 2016; Crossfield & Kreidberg 2017; Fu et al. 2017). Our results add to studies using simulated JWST observations (Wakeford & Sing 2015; Pinhas & Madhusudhan 2017; Mai & Line 2019; Lacy & Burrows 2020).
2. In order for retrievals to obtain accurate abundance estimates with JWST observations in the $\sim 3\text{--}5\ \mu\text{m}$ range, complementary observations may be needed at shorter wavelengths. This allows retrievals to constrain the spectral baseline needed for accurate and precise estimates of molecular abundances. Specifically, we find that complementary observations with HST/WFC3 can be highly effective for this goal, resulting in changes in the retrieved abundances by up to 1 dex in some cases, compared to retrievals using $\sim 3\text{--}5\ \mu\text{m}$ spectra alone.
3. JWST observations over a wide wavelength range can in principle constrain the presence of clouds/hazes, as well as their specific nature, e.g., particle composition and size. This has been previously considered with simulated

JWST observations (e.g., Benneke & Seager 2013; Wakeford & Sing 2015; Pinhas & Madhusudhan 2017; Mai & Line 2019; Lacy & Burrows 2020) and with HST-era observations (Benneke et al. 2019). It is therefore important that atmospheric retrievals have the capability to properly treat the complex spectral signatures that aerosols can contribute to a planet's transmission spectrum.

4. As expected from prior theoretical works, JWST transmission spectra in the near-infrared can provide precise abundance constraints for several prominent molecules in exoplanetary atmospheres (e.g., Beichman et al. 2014; Greene et al. 2016; Howe et al. 2017; Bean et al. 2018; Kalirai 2018). For the present case, we retrieve abundance constraints with a precision of $\sim 0.3\text{--}0.5$ dex for prominent molecules, even with the relatively limited spectral range considered. Combining this data with other JWST observations can lead to even more precise abundance constraints.
5. Small differences in JWST spectra, such as those arising due to different reduction pipelines, can have a notable impact on the retrieved constraints and detections, particularly for less prominent species. This is thanks to the high precision that JWST observations can have, especially for giant exoplanets. For the case of the WASP-39 b observations we consider, which are for a single transit, we find that differences in spectra arising from differences between reduction pipelines can affect which species are detected at a $2\sigma\text{--}3\sigma$ level. Therefore, robust data reduction pipelines are needed in order to converge on accurate chemical detections.
6. A high detection significance for a particular chemical species does not indicate that its abundance is constrained accurately. For instance, retrieving on JWST/NIRSpec PRISM observations obtained with the Tiberius pipeline leads to a $\sim 25\sigma$ detection significance. However, on supplementing these observations with HST/WFC3 G141 and G102 data, the retrieved mixing ratio estimate is 1 dex higher, as the retrieval finds a different spectral baseline.
7. The precision with which the abundance of a chemical species is constrained is not indicative of how confidently it is detected. For instance, using JWST NIRSpec PRISM observations reduced with the Tiberius pipeline, we constrain the mixing ratios of CO_2 and H_2S with a precision of $\lesssim 0.4$ dex. While CO_2 is detected with extremely high confidence, H_2S , however, is not, with our retrievals finding only a tentative 2σ model preference for its inclusion. It is therefore essential that future studies assess the robustness of their findings by carrying out a full Bayesian model comparison for each chemical species that may be detected.
8. The spectral ranges of JWST instruments allow for the detection of chemical species that have not been hitherto considered in exoplanet retrievals, and potentially chemical processes that may have not been anticipated. In the present example of WASP-39 b, we independently confirm the presence of SO_2 reported by Rustamkulov et al. (2022) and Alderson et al. (2022), while also finding tentative indications of H_2S . We therefore find that retrieval frameworks must be open to diverse chemistry if

Figure 5. Initial constraints on the elemental abundances in the atmosphere of WASP-39 b. The O/H (blue), C/H (red), and S/H (yellow) ratios are derived from the molecular abundances retrieved from JWST data in the 3–5 μm range combined with HST/WFC3 data (0.8–1.7 μm). The elemental abundances are shown relative to solar values (Asplund et al. 2021). The dashed vertical line denotes the planet mass (0.28 M_J). Closed and open circles within the gray shaded region refer to retrievals using JWST data from the Tiberius and Eureka pipelines, respectively, offset horizontally for clarity. The C/H abundances for solar system giant planets (Atreya et al. 2022) along with a linear fit (in brown) and the O/H in Jupiter from Juno (Li et al. 2020) are shown for reference.

they are to be capable of fully taking advantage of JWST observations.

5.2. The Atmosphere of WASP-39 b

In light of the above considerations, we present initial constraints on the atmospheric properties of WASP-39 b. We confirm the presence of CO_2 , CO , and SO_2 reported by The JWST Transiting Exoplanet Community Early Release Science Team et al. (2022), Rustamkulov et al. (2022), and Alderson et al. (2022). We additionally find tentative indications for the presence of H_2S , with detection significances between $\sim 2\sigma$ and 4σ across our retrievals. Our abundance estimate of SO_2 supports prior findings of disequilibrium chemistry at work in the atmosphere of WASP-39 b (Tsai et al. 2022). Additionally, the presence of H_2S suggested by our retrievals further supports this, as H_2S is expected to be the primary sulfur reservoir under chemical equilibrium deeper in the atmosphere (Zahnle et al. 2009; Wang et al. 2017; Hobbs et al. 2021; Polman et al. 2022), which photochemically reacts with H_2O in the upper atmosphere to form SO_2 .

As our retrievals obtain abundance constraints for a range of oxygen-, carbon-, and sulfur-bearing species, we can begin to probe the relative enrichment of each element in the atmosphere of WASP-39 b, as shown in Figure 5. Considering the constraints obtained with JWST observations reduced by the Tiberius pipeline combined with HST/WFC3 data, we find that the inferred O/H, C/H, and S/H values correspond to $15_{-10}^{+30} \times$, $21_{-14}^{+46} \times$, and $17_{-7}^{+15} \times$ solar enrichments, respectively (Asplund et al. 2021). Such enhancements are consistent with the atmospheric metallicity of Saturn based on CH_4 measurements, at $8.67 \pm 0.35 \times$ solar, and with recent suggestions for WASP-39 b (Alderson et al. 2022; Feinstein et al. 2022; Rustamkulov et al. 2022). Meanwhile, the equivalent O/H, C/H, and S/H inferences using JWST observations reduced with the Eureka pipeline and HST/WFC3 data correspond to

$4_{-2}^{+6} \times$, $2_{-1}^{+4} \times$, and $11_{-7}^{+11} \times$ solar enrichments. In this case, the oxygen and sulfur enrichments are still consistent with the metallicity of Saturn, while carbon is somewhat less enriched. We note that the uncertainties in our O/H and C/H estimates are primarily driven by the CO mixing ratio constraints, which are retrieved with precisions of ~ 0.4 – 0.5 dex. Retrievals combining the present JWST/NIRSpec PRISM data with recently published NIRSpec G395H observations (Alderson et al. 2022) that also encompass the $\sim 4.8 \mu\text{m}$ CO feature may further refine the present estimates.

Beyond constraints for gaseous species, we also obtain tentative indications of non-gray opacity contributions from Mie-scattering aerosols. Specifically, our retrieval on JWST data reduced with the Tiberius pipeline and HST/WFC3 observations infers the presence of MgSiO_3 aerosols. These aerosols are found to have a modal particle size of ~ 2 nm and cover $\sim 50\%$ of the planet’s terminator. Meanwhile, retrieving on JWST data from Eureka and HST/WFC3 observations, we find tentative indications of ZnS aerosols instead. These compositional constraints are consistent with thermochemical expectations for condensing species (Morley et al. 2013). Our findings are also in agreement with preferences for non-gray spectral contributions from aerosols obtained with a forward model analysis of NIRISS observations (Feinstein et al. 2022).

Our retrievals also lead to constraints for the planet’s terminator temperature. Using the Tiberius reduction of the JWST data along with HST/WFC3 data, we find tentative indications of a nonisothermal temperature, with a temperature of 757_{-43}^{+40} K at the top of the atmosphere. Meanwhile, JWST data from Eureka and HST/WFC3 observations instead lead to a P-T profile that is consistent with an isotherm, with a temperature of 666_{-72}^{+53} K.

WASP-39 b and its ERS observations are set to allow an in-depth comparison between a solar-system planet and an extrasolar planet. Our results contribute an early step toward a next-generation comparative study between Saturn and an exoplanet that is a near-Saturn analog in both mass and metallicity.

The results presented above are only initial constraints for the atmospheric properties of WASP-39 b, obtained with a relatively limited spectral range of JWST observations (~ 3 – $5 \mu\text{m}$). Future retrievals with all available data (~ 0.6 – $5 \mu\text{m}$) can significantly improve upon the constraints presented in this work. However, our study highlights the need for rigorous data reduction and retrieval considerations as well as a robust exploration of the available parameter space. The retrievals in this work involved $\sim 10^9$ model evaluations to achieve that goal.

In addition to physically motivated aerosol considerations, future retrievals may also consider the effect of inhomogeneous temperature (Nixon & Madhusudhan 2022) and chemical (Rocchetto et al. 2016) structures, as well as the impact of stellar heterogeneity aided by optical data (Rackham et al. 2017; Pinhas et al. 2018) and other molecular opacity sources. While such model sophistication may not be applicable in all cases, especially for moderately irradiated planets like WASP-39 b, a holistic approach is recommended for accurate retrievals of atmospheric properties in the JWST era.

Our results provide a glimpse into the richness of atmospheric science that JWST is set to enable, thanks to its unprecedented sensitivity and wide spectral coverage that includes hitherto unexplored wavelengths. Our results also

highlight the sophistication demanded of atmospheric models and retrievals, as well as the robustness required of reduction pipelines, if we are to rise to the challenge and make full use of the discovery opportunities that JWST presents.

This work was performed using resources provided by the Cambridge Service for Data Driven Discovery (CSD3) operated by the University of Cambridge Research Computing Service (www.csd3.cam.ac.uk), provided by Dell EMC and Intel using Tier-2 funding from the Engineering and Physical Sciences Research Council (capital grant EP/P020259/1), and DiRAC funding from the Science and Technology Facilities Council (www.dirac.ac.uk). This work uses data reduced from observations with the NASA/ESA/CSA JWST, as part of The Transiting Exoplanet Community Early Release Science (ERS) Program (PI: N. Batalha). We thank NASA, ESA, CSA, STScI, the ERS team, and everyone

whose efforts have contributed to JWST and exoplanet science with JWST.

We thank the anonymous referee for their valuable comments. S.C. thanks Anjali Piette for helpful discussion on Mie scattering. N.M. acknowledges support from the MERAC Foundation, Switzerland and the UK Science and Technology Facilities Council (STFC). S.G. is grateful to Leiden Observatory at Leiden University for the award of the Oort Fellowship.

Appendix

Figure 6 shows the spectral contributions from gaseous species in our retrieved best-fit spectrum, obtained for JWST/NIRSpec PRISM observations reduced with Tiberius and HST/WFC3 data. We note that this figure does not include spectral contributions from MgSiO_3 aerosols, for visual clarity. As such, the combined spectral contributions correspond to the blue curve in Figure 1.

Figure 6. The spectral contributions from H_2O , CO , CO_2 , SO_2 , and H_2S to the best-fit spectrum obtained from the retrieval on JWST observations reduced by the Tiberius pipeline combined with HST/WFC3 data. Also shown is the resulting spectrum from all molecular spectral contributions, corresponding to the aerosol-free model shown in Figure 1. Spectral contributions from MgSiO_3 aerosols as shown in Figure 1 are not included here, for visual clarity.
