ABSTRACT *Bacillus Calmette-Guerin (BCG) vaccination has been hypothesized to reduce severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, severity, and/or duration via trained immunity induction. Health care workers (HCWs) in nine Dutch hospitals were randomized to BCG or placebo vaccination (1:1) in March and April 2020 and followed for 1 year. They reported daily symptoms, SARS-CoV-2 test results, and health care-seeking behavior via a smartphone application, and they donated blood for SARS-CoV-2 serology at two time points. A total of 1,511 HCWs were randomized and 1,309 analyzed (665 BCG and 644 placebo). Of the 298 infections detected during the trial, 74 were detected by serology only. The SARS-CoV-2 incidence rates were 0.25 and 0.26 per person-year in the BCG and placebo groups, respectively (incidence rate ratio, 0.95; 95% confidence interval, 0.76 to 1.21; $P = 0.732$). Only three participants required hospitalization for SARS-CoV-2. The proportions of participants with asymptomatic, mild, or moderate infections and the mean infection durations did not differ between randomization groups. In addition, unadjusted and adjusted logistic regression and Cox proportional hazards models showed no differences between BCG and placebo vaccination for any of these outcomes. The percentage of participants with seroconversion (7.8% versus 2.8%; $P = 0.006$) and mean SARS-CoV-2 anti-S1 antibody concentration (13.1 versus 4.3 IU/mL; $P = 0.023$) were higher in the BCG than placebo group at 3 months but not at 6 or 12 months postvaccination. BCG vaccination of HCWs did not reduce SARS-CoV-2 infections nor infection duration or severity (ranging from asymptomatic to moderate). In the first 3 months after vaccination, BCG vaccination may enhance SARS-CoV-2 antibody production during SARS-CoV-2 infection.*

IMPORTANCE While several BCG trials in adults were conducted during the 2019 coronavirus disease epidemic, our data set is the most comprehensive to date, because we included serologically confirmed infections in addition to self-reported positive SARS-CoV-2 test results. We also collected data on symptoms for every day during the 1-year follow-up period, which enabled us to characterize infections in detail. We found that BCG vaccination did not reduce SARS-CoV-2 infections nor infection duration or severity but may have enhanced SARS-CoV-2 antibody production during SARS-CoV-2 infection in the first 3 months after vaccination. These results are in agreement with other BCG trials that reported negative results (but did not use serological endpoints), except for two trials in Greece and India that reported positive results but had few endpoints and included endpoints that were not laboratory confirmed. The enhanced antibody production is in agreement with prior mechanistic studies but did not translate into protection from SARS-CoV-2 infection.

KEYWORDS SARS-CoV-2, COVID-19, Bacillus Calmette-Guerin vaccine, randomized placebo-controlled clinical trial, health care workers

The Bacillus Calmette-Guerin (BCG) vaccine is a widely used live-attenuated vaccine against tuberculosis. Routine childhood and/or health care worker (HCW) vaccination is performed worldwide, except in some countries with a low tuberculosis burden, including the Netherlands. New interest in BCG has arisen after recent studies showed that BCG vaccination also has nonspecific protective effects against other respiratory tract infections due to epigenetic and metabolic reprogramming of innate immune cells (1, 2). This process is termed “trained immunity.” It was first observed in children in high-infection prevalence settings (3), but later also in observational studies in adults (4, 5) and in adults challenged with malaria or live-attenuated yellow fever or influenza vaccination after BCG vaccination (6–8).

In the first year of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic, testing and contact-tracing capacity, as well as personal protection equipment supplies, were limited and SARS-CoV-2 vaccines were not yet available. These conditions raised challenges, especially for HCWs and vulnerable adults. HCWs were burdened with a high risk of exposure and infection while the demand for medical personnel increased (9–11), and vulnerable adults were at high risk of hospitalization and death. However, BCG vaccines were available. In this context, several randomized placebo-controlled BCG trials with 2019 coronavirus disease (COVID-19) endpoints were initiated during the pandemic to determine whether BCG vaccination reduced SARS-CoV-2 infection and/or infection severity or duration.

We recently published the results of the BCG-Corona trial in 1,511 Dutch HCWs (12). The primary endpoint of this trial was absenteeism for any reason. Secondary endpoints were, among others, participant-reported positive SARS-CoV-2 tests and symptomatic respiratory infections. None of these endpoints differed statistically significantly between the BCG and placebo groups. However, while participants were instructed to always get tested in case of COVID-19-like symptoms, they may not always have done so, especially in the case of mild infections. Furthermore, asymptomatic infections likely went unnoticed. We therefore also collected blood samples for SARS-CoV-2 antibody testing at 3 to 6 months and 12 months postvaccination. This uncovered 74 additional infections in addition to the 224 participant-reported infections. Our aim was to determine whether BCG vaccination compared to placebo vaccination reduced SARS-CoV-2 infection acquisition, severity, and/or duration using this most comprehensive data set in the field to date, with endpoints detected by both self-reporting and serology and with daily data on symptoms.

RESULTS

Participant flow and baseline characteristics. Between 24 March and 23 April 2020, 1,526 HCWs were screened and 1,511 were randomized, with 753 HCWs in the BCG group and 758 in the placebo group (Fig. 1). Participants with less than 80% app

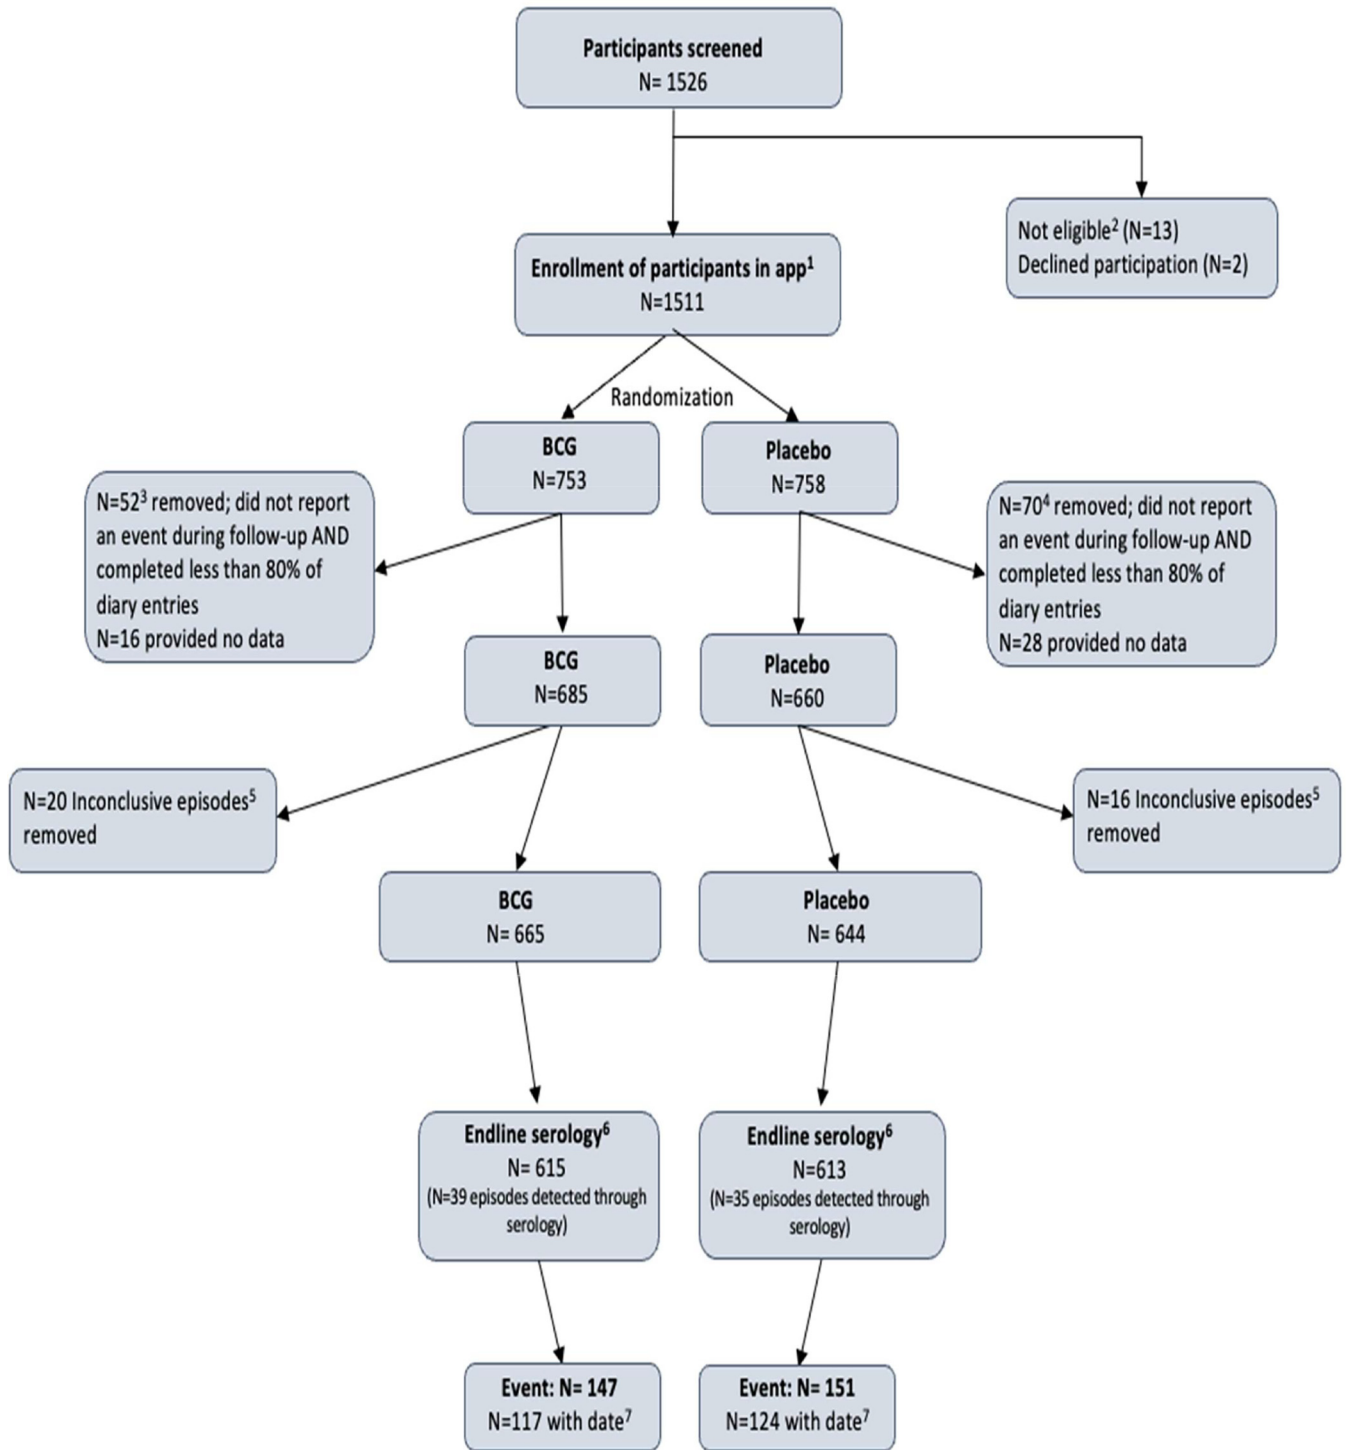

FIG 1 BCG-Corona Study flow. Footnotes: (1) The first participant was enrolled on 24 March 2020 and the last participant on 23 April 2020. The last day of follow-up in the app was 27 March 2021, with additional participant information obtained via an online questionnaire to cover the period between 28 March 2021 and the last blood sampling date, if applicable. (2) Thirteen participants were not eligible: pregnancy ($N = 4$), severely immunocompromised state ($N = 1$), malignancy or lymphoma in the last 2 years ($N = 1$), active viral or bacterial infection ($N = 2$), recent or expected vaccination ($N = 3$), not hospital personnel caring for COVID-19 patient ($N = 1$), or *Mycobacterium tuberculosis* infection history ($N = 1$). (3) Of the 52 participants in the BCG group removed due to less than 80% diary app completion and no evidence of infection, 19 terminated study participation early at their own request, 10 became complete nonresponders prior to the end of the study for unknown reasons, 2 went on pregnancy leave, and 21 entered data inconsistently. An additional 16 participants never entered any data in the app. (4) Of the 70 participants in the placebo group removed due to less than 80% diary app completion and no evidence of infection, 33 terminated study participation early at their own request, 10 became complete nonresponders prior to the end of the study for unknown reasons, 6 terminated hospital employment, 3 went on pregnancy leave, and 18 entered data inconsistently. An additional 28 participants never entered any data in the app. The percentage of participants that completed less than 80% of the diary entries in the BCG group was not (Continued on next page)

completion and no evidence of infection (see Fig. S1 in the supplemental material), or with inconclusive episodes only, were removed (68 and 20 in the BCG group and 98 and 16 in the placebo group, respectively). The analysis population therefore consisted of 1,309 participants: 665 in the BCG group and 644 in the placebo group. Of the analysis population, 82.9% in the BCG group and 85.7% in the placebo group provided a blood sample in the second sampling round. An additional 9.6% and 9.5%, respectively, provided a blood sample in the first but not in the second sampling round. None of the data availability characteristics differed significantly between the randomization groups (Fig. 1).

The majority of the 1,309 participants (74.4%) were female, with no difference between groups (Table 1). The age of participants ranged between 18 and 67 years, with mean ages of 41.8 years in the BCG group and 43.2 years in the placebo group. Job-related characteristics were also similar between groups: 49.3% of the participants were nurses and 53.1% reported to have direct patient contact at least 75% of their work hours. Household size, smoking behavior, histories of BCG or recent influenza or other vaccinations, ever having had a positive tuberculosis test, having had a respiratory tract infection last winter, and chronic comorbidities were well-balanced between groups. The baseline characteristics of the analysis population were comparable to those of the entire randomized population (Table S1A). Some significant differences in baseline characteristics were observed between participants recruited at the three core hospitals versus the six other hospitals, but this did not affect the BCG-placebo comparisons because randomization was stratified by hospital (Table S1B). About half of the participants (47.2% in the BCG group and 50.6% in the placebo group; $P = 0.218$) received at least one dose of one of five different COVID-19 vaccines between 6 January 2021 and the end of follow-up. The time to first COVID-19 vaccination did not differ between the randomization groups (Fig. 2).

Descriptive outcomes by randomization group. SARS-CoV-2 infections over calendar time in the study population mirrored epidemic waves in the Netherlands (Fig. S2). Only one participant (in the BCG group) reported to have had a positive SARS-CoV-2 test prior to randomization. A total of 298 infections (not including 4 second infections) were detected during the trial, of which 224 were participant reported and 74 detected by serology only (Table 2). Overall, 147/665 participants (22.1%) in the BCG group and 151/644 participants (23.4%) in the placebo group experienced an infection during follow-up ($P = 0.608$). The SARS-CoV-2 incidence was 0.25 per person-year in the BCG group and 0.26 per person-year in the placebo group (incidence rate ratio, 0.95; 95% confidence interval [CI], 0.76 to 1.21; $P = 0.732$) (Table S2).

In the BCG and placebo groups, respectively, 0.7% and 1.3% of first infections were moderate, 73.5% and 76.8% were mild (of which 18.4% and 22.5% were mild and 55.1% and 54.3% were very mild), and 15.6% and 12.6% were asymptomatic (no statistically significant differences) (Table 2). As expected, most symptomatic infections were identified via participant reporting: 92.0% of mild and 100% of moderate episodes. In contrast, 76.2% of the asymptomatic episodes were identified by serology only. Fifteen episodes in the BCG group (10.8%) and 12 in the placebo group (8.3%) reached the long-COVID definition during follow-up ($P = 0.616$). In addition, four (2.8%) and eight (5.4%) episodes in the BCG and placebo groups, respectively, resulted in long-term loss of smell and/or taste ($P = 0.431$) (Table 2). The mean episode durations of acute episodes (not including long-COVID or asymptomatic episodes) were 15.4 days (standard deviation [SD], 10.1 days) in the BCG group and 15.9 days (SD 11.4 days) in the placebo group ($P = 0.890$) (Table 2, Fig. S3). None of the different types of symptoms, nor their individual severities, differed between randomization groups (Table S2).

FIG 1 Legend (Continued)

statistically different from the percentage in the placebo group (chi-squared $P = 0.283$). (5) An inconclusive episode was defined as anti-N seropositivity but not anti-S1 seropositivity at the end of period 2. The percentage of participants that we removed from the BCG group because they had inconclusive episodes only was not statistically different from the percentage in the placebo group (chi-squared $P = 0.599$). (6) N is the number of participants that participated in at least one sampling round at the end of the follow-up (chi-squared $p = 0.237$). (7) Events with a date were included in all analyses and events without a date in logistic regressions only.

^aChi-squared tests for categorical variables and Wilcoxon rank sum test for continuous variables.

^bThe 1.42 years difference in mean age was statistically significant, but we believe that it was not relevant in this context.

^cInternal medicine includes the pulmonology and infectious disease departments.

^dTuberculosis tests included the Mantoux and/or TB QuantiFERON tests.

^eThe following other vaccinations were reported: diphtheria-tetanus-pertussis-polio (DTaP-IPV), hepatitis A, hepatitis B, yellow fever, typhoid, rabies, mumps-measles-rubella, meningococcal, pneumococcal, *Haemophilus influenzae* type B, Ebola, tick-borne encephalitis, human papillomavirus, and unknown.

^fIn the Netherlands, the SARS-CoV-2 vaccines available during the study period were Spikevax (Moderna Biotech, Cambridge, MA, USA), Comirnaty (Pfizer/BioNTech, New York, NY, USA), Vaxzevria (AstraZeneca AB, Sodertalje, Sweden), and Jcovden (Janssen Vaccines, Leiden, Netherlands). In addition, one participant received an experimental vaccine by CureVac N.V. in a clinical trial setting. This vaccine was never marketed due to insufficient efficacy. See Table S1 in the supplemental material for the number and percentage of participations in each vaccine category by randomization group.

About a quarter of all infections (24.8%) was identified by serology only, and this percentage was non-significantly higher in the BCG group in period 1 (50.9%) compared to the BCG group in period 2 (10.0%) and or to the placebo group in both periods (29.4% and 19.3%) (Table 2). Seroidentified episodes accumulated faster in the BCG than in the placebo group (logrank $P = 0.002$, Fig. 2). The percentage of participants with seroconversion was higher in the BCG group than in the placebo group at month 3 (7.8% versus 2.8%; $P = 0.006$), but not at month 6 (8.8% versus 7.0%; $P = 0.573$) or month 12 (13.6% versus 15.6%; $P = 0.401$). Similarly, the mean anti-S1 antibody concentration was higher in the BCG group than in the placebo group at month 3, but there were no differences in anti-S1 or anti-N antibody concentrations between the groups at months 6 or 12 (Table 2).

Logistic regression and Cox proportional hazards models. Unadjusted and adjusted logistic regression models showed no differences between BCG and placebo vaccination in cumulative incidence of any SARS-CoV-2 infection or of asymptomatic, mild (subdivided into mild and very mild), or moderate infections separately (Table 3). No differences were seen in Cox proportional hazards time-to-first-event models with these same outcomes, either (Table 3, Fig. 2). Younger age, various job-related characteristics, past BCG vaccination, and current use of hypertension medication were associated with increased odds or hazards of acquiring infection (Table S3) and were retained in all multivariable models (Table 3, Table S4). A larger household size was associated with increased odds or hazards in some but not all models. In terms of job-related characteristics, being a nurse or support staff (compared to a doctor), having a larger percentage of work hours with patient contact, and expectation to work on a COVID ward were associated with higher odds or hazards of infection or infection severity, and working in the intensive or medium care departments (compared to the urgent care department) were associated with lower odds or hazards. Recruitment site, enrollment week, sex, ever having tested positive for tuberculosis, current use of anti-diabetic medication, history of pulmonary disease, and history of cardiovascular disease were not associated with an outcome in any of the models. All sensitivity analyses showed similar results (Tables S5 and S6).

DISCUSSION

This is the most comprehensive analysis of a placebo-controlled BCG trial with SARS-CoV-2 endpoints to date, including both participant-reported positive tests as well as serology to identify infections and in-depth characterization of infection

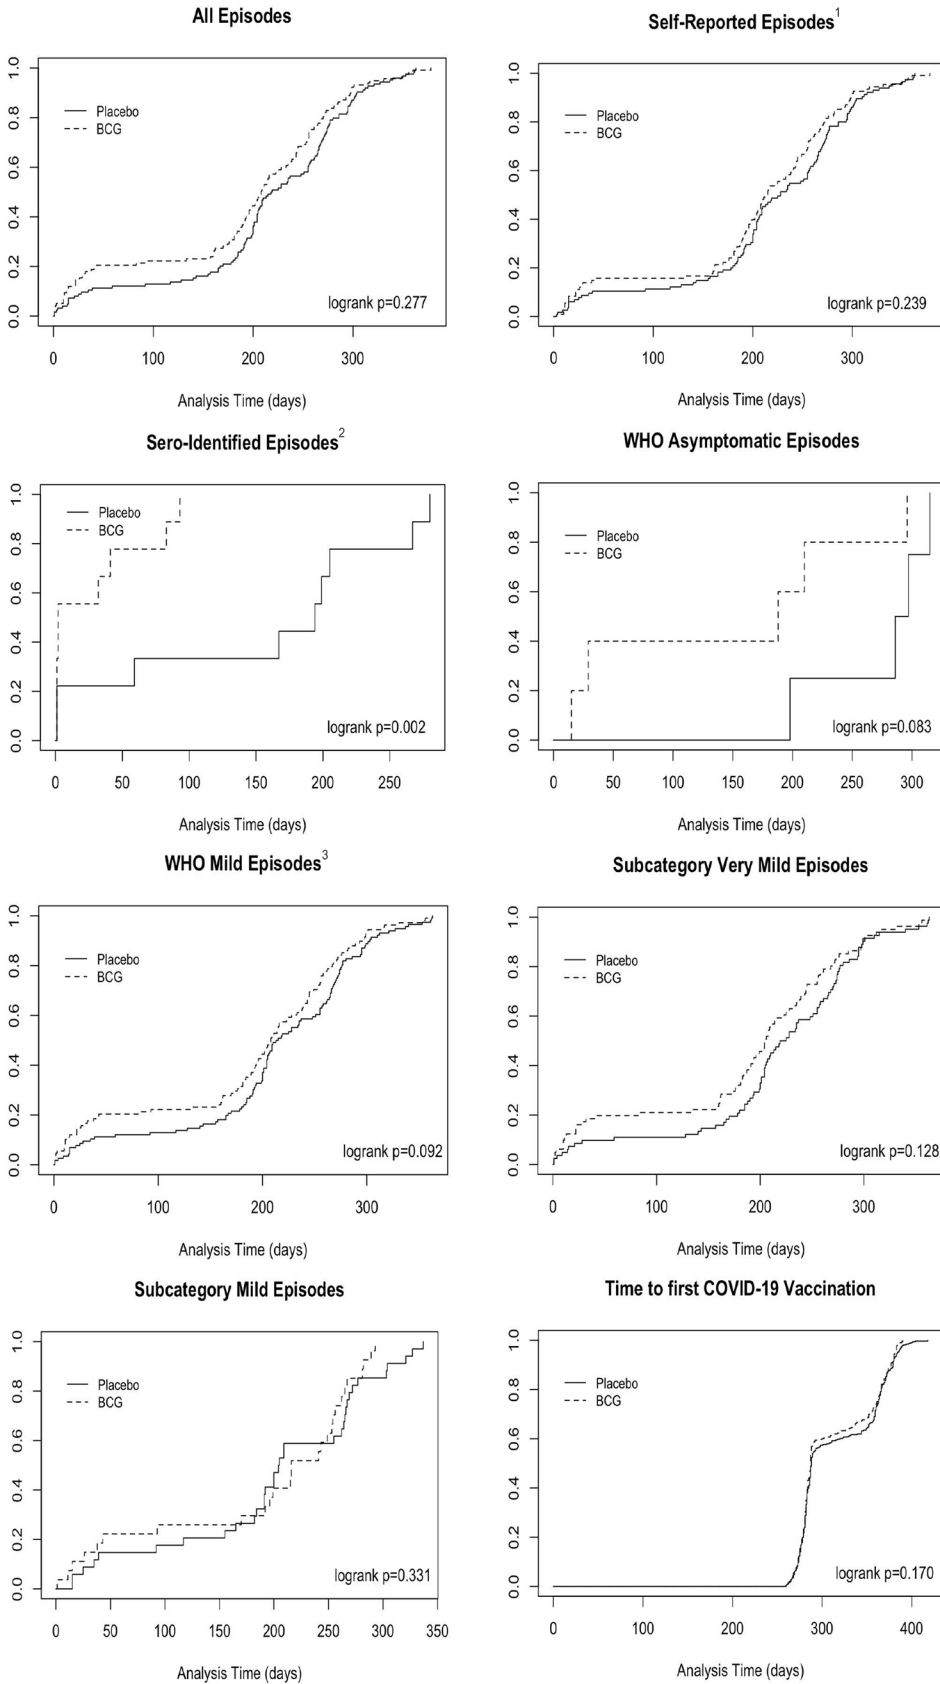

FIG 2 Time-to-first event curves. Footnotes: (1) Self-reported episodes included proven episodes with and without seroconversion. (2) Sero-identified episodes included all possible episodes detected through (Continued on next page)

episodes using daily symptoms data. Serology detected an additional 74 endpoints on top of the 224 participant-reported endpoints. Unadjusted and adjusted logistic regression (cumulative incidence) and Cox proportional hazards (time-to-first-event) models showed no differences between BCG and placebo vaccination for SARS-CoV-2 infections of any severity, nor for asymptomatic, mild (subdivided into mild and very mild), or moderate infections separately. Mean infection durations and the proportions of participants with infections who developed long-COVID or long-term loss of smell and/or taste did not differ between the randomization groups either.

Our findings corroborated the results of several placebo-controlled BCG trials with SARS-CoV-2 endpoints. A South African trial in HCWs ($N = 1,000$) (13) and two Dutch trials in community-dwelling elderly populations ($N = 2,014$) (14) and vulnerable elderly populations ($N = 6,112$) (15) found no differences between BCG and placebo vaccination in participant-reported positive SARS-CoV-2 tests, COVID-19 hospitalizations or deaths, or any symptomatic respiratory tract infection in the year following vaccination. The South African trial did not detect a difference in the cumulative incidence of SARS-CoV-2 seroconversion either, but it is unclear how seroconversion was defined, and seroconversions due to natural infection versus COVID-19 vaccination were not differentiated (13). The ACTIVATE-2 trial in older Greek patients ($N = 153$) did report a protective effect of BCG vaccination (odds ratio [OR] 0.32; 95% CI, 0.13 to 0.79), but the trial endpoint combined test-confirmed and suspected COVID-19 cases (16). A trial in India ($N = 495$) reported a protective effect for suspected COVID-19 cases (OR, 0.38; 95% CI, 0.20 to 0.72) but not for test-confirmed cases (OR, 1.08; 95% CI, 0.54 to 2.14) (17). It has been hypothesized that childhood BCG vaccination and/or latent tuberculosis might modulate BCG-induced trained immunity (18). Childhood vaccination is common in South Africa, Greece, and India but not in the Netherlands. Latent tuberculosis is more prevalent in South Africa than in Greece (48.5% and 5.8% in the South African and Greek trial populations, respectively) (4, 13), and uncommon in the Netherlands. It therefore seems unlikely that these factors explain the divergent results of the Greek and Indian versus South African and Dutch trials, but ongoing trials in additional populations might shed more light on this debate in the future (19, 20). We think that it is more likely that endpoints based on suspected COVID-19 cases are insufficiently specific for SARS-CoV-2 infection and that the total number of endpoints in the Greek and Indian trials was too small to rule out chance (16, 17).

SARS-CoV-2 risk in HCWs increased with the proportion of work hours with patient contact. This suggests that the risk is mostly due to a high probability of exposure rather than a higher risk of infection once exposed. Interestingly, working in intensive or medium care unit was associated with a lower risk of infection than working in urgent care, which may be related to better infection control measures, including availability of personal protective equipment, in the former. Using antihypertensive medication was also consistently associated with higher infection risk. Patients diagnosed with high blood pressure have increased levels of angiotensin-converting enzyme 2 (ACE2), which acts as the entry receptor for SARS-CoV-2 (21, 22). Whether antihypertensive medication use has an additional effect is controversial: animal models have suggested an increase in ACE2 in the respiratory tract due to these medications but an increased SARS-CoV-2 infection risk after medication initiation has not been confirmed in humans (23, 24). Finally, our data confirmed that a substantial proportion of SARS-CoV-2 infections (14.1%) are asymptomatic and that HCWs are less likely to seek testing for asymptomatic or very mild infections than for mild or moderate infections.

The BCG-Corona trial was initiated in March 2020, early in the first epidemic wave in the Netherlands, and therefore captured SARS-CoV-2 exposures and infections in an

FIG 2 Legend (Continued)

serology that could be linked to a symptomatic period and therefore had a known episode infection date. (3) WHO mild episodes were further subcategorized into very mild and mild episodes (definitions can be found in Text S1 in the supplemental material). The WHO moderate episodes are not shown in time-to-event curves because there were only three episodes.

TABLE 2 Outcomes during follow-up, by randomization group

| Outcome | BCG (N = 665) | Placebo (N = 644) | Total (N = 1,309) | P ^a |
|--|-------------------|---------------------|-------------------|----------------|
| Reported a positive test during follow-up, n (%) | 108 (16.3) | 116 (18.0) | 224 (17.1) | 0.528 |
| All episodes based on reported tests and serology during follow-up, n (%) | 147 (22.1) | 151 (23.4) | 298 (22.8) | 0.608 |
| Episode severity (WHO definitions), n (%) | | | | 0.806 |
| Asymptomatic | 23 (15.6) | 19 (12.6) | 42 (14.1) | |
| Mild | 108 (73.5) | 116 (76.8) | 224 (75.2) | |
| Moderate | 1 (0.7) | 2 (1.3) | 3 (1.0) | |
| Unknown | 15 (10.2) | 14 (9.3) | 29 (9.7) | |
| Episode severity with subcategories, n (%) ^b | | | | 0.823 |
| Asymptomatic | 23 (15.6) | 19 (12.6) | 42 (14.1) | |
| Very mild | 81 (55.1) | 82 (54.3) | 163 (54.7) | |
| Mild | 27 (18.4) | 34 (22.5) | 61 (20.5) | |
| Moderate | 1 (0.7) | 2 (1.3) | 3 (1.0) | |
| Unknown | 15 (10.2) | 14 (9.3) | 29 (9.7) | |
| Long-term loss of smell and/or taste, n (%) ^c | 4 (2.8) | 8 (5.4) | 12 (4.1) | 0.431 |
| Developed long-COVID, n (%) ^d | 15 (10.8) | 12 (8.3) | 27 (9.5) | 0.616 |
| Mean (SD) duration of acute episode ^e | 12.24 (10.93) | 13.38 (11.96) | 12.84 (11.47) | 0.590 |
| Mean (SD) duration of acute episode, excluding asymptomatic and long-COVID episodes ^f | 15.44 (10.06) | 15.90 (11.40) | 15.68 (10.76) | 0.890 |
| Episode type, n (%) | | | | 0.008 |
| Participant-reported with seroconversion | 71 (48.3) | 78 (51.7) | 149 (50.0) | |
| Participant-reported with no seroconversion | 12 (8.2) | 27 (17.9) | 39 (13.1) | |
| Participant-reported and no serology | 25 (17.0) | 11 (7.3) | 36 (12.1) | |
| Identified by seroconversion only | 39 (26.5) | 35 (23.2) | 74 (24.8) | |
| Period that episode occurred in and data source, n (%) ^g | | | | 0.075, 0.108 |
| Period 1: participant reported | 28 (49.1) | 24 (70.6) | 52 (57.1) | |
| Period 1: sero-identified only | 29 (50.9) | 10 (29.4) | 39 (42.9) | |
| Period 2: participant reported | 80 (90.0) | 92 (80.7) | 172 (84.7) | |
| Period 2: sero-identified only | 9 (10.0) | 22 (19.3) | 31 (15.3) | |
| Unknown period | 1 (0.7) | 3 (2.0) | 4 (1.3) | |
| Antibody results for participants with samples available ^h | | | | |
| No. (%) with anti-S1 antibodies at mo. 3; total group N | 27 (7.8); 344 | 9 (2.8); 325 | 36 (5.4); 669 | 0.006 |
| Mean (SD) anti-S1 concn at mo. 3 (IU/mL) | 13.05 (64.87) | 4.34 (23.61) | 8.82 (49.50) | 0.023 |
| No. ⁱ (%) with anti-S1 antibodies at mo. 6; total group N | 21 (8.8); 238 | 16 (7.0); 229 | 37 (7.9); 467 | 0.573 |
| Mean (SD) anti-S1 concn at mo. 6 (IU/mL) | 11.37 (50.74) | 13.67 (79.57) | 12.50 (66.40) | 0.709 |
| No. ^j (%) with anti-S1 antibodies at round 1; total group N | 48 (8.2); 582 | 25 (4.5); 553 | 73 (6.4); 1,135 | 0.015 |
| Mean (SD) anti-S1 concn at Round 1 (IU/mL) | 12.37 (59.45) | 8.21 (54.44) | 10.34 (57.08) | 0.220 |
| No. ^k (%) with anti-S1 + anti-N antibodies at round 2; total group N | 75 (13.6); 551 | 86 (15.6); 552 | 161 (14.6); 1,103 | 0.401 |
| Mean (SD) anti-S1 concn at round 2 (IU/mL) | 902.51 (2,690.39) | 1,007.96 (2,765.13) | 955.28 (2,727.32) | 0.521 |
| Mean (SD) anti-N concn at round 2 (IU/mL) | 17.61 (72.10) | 16.28 (68.56) | 16.94 (70.32) | 0.752 |

^aBased on chi-square test for categorical variables and Wilcoxon rank sum test for means. P values of <0.05 are indicated in boldface.

^bWe further subdivided the WHO "mild" category into very mild and mild subcategories (see the definitions in Text S1 in the supplemental material).

^cReported stand-alone loss of smell and/or taste for at least 60 days after the end of acute infection episode. The denominators are 141, 149, and 290 for BCG, placebo, and total, respectively, because 6, 2, and 8 episodes that had not yet reached 60 days of stand-alone loss of smell and/or taste but were ongoing at the end of follow-up were excluded.

^dReported symptoms other than stand-alone loss of smell and/or taste for at least 60 days after the end of acute infection episode. The denominators are 139, 144, and 283 for BCG, placebo, and total, respectively, because 8, 7, and 15 episodes that had not yet reached 60 days of lingering symptoms other than stand-alone loss of smell and/or taste but were ongoing at the end of follow-up were excluded.

^eN = 231 episodes. The following episodes were removed from the calculations: 27 long-COVID cases, 15 episodes that had not yet reached the long-COVID definition but were ongoing at the end of follow-up, and 25 episodes that could not be matched with one specific symptoms episode and therefore had an unknown episode duration. In cases of lingering stand-alone loss of smell and/or taste, only the duration of the acute infection episode (with respiratory tract symptoms) was included.

^fN = 189 episodes. The same episodes as listed under footnote e were removed from the calculations, as were 42 asymptomatic episodes with a duration of 0 days.

^gPeriod 2 data included period 1 if only one sample (at the end of period 2) was taken. Four episodes (one in the BCG group and three in the placebo group) could not be assigned to a period. The first P value compares the distribution between participant-reported and sero-identified episodes in the BCG and placebo groups during period 1, and the second P value for episodes in period 2. Four episodes (one in the BCG group and three in the placebo group) could not be assigned to a period and were excluded from both statistical tests.

^hN is the total participants in the denominator. Participants who did not volunteer a blood sample at the given sampling round or were not offered blood sampling in their hospital were removed. Comparison of baseline characteristics between serology cohorts at month 3 (core hospitals) and month 6 (other hospitals) are shown in Table S1B in the supplemental material.

ⁱIncludes core hospital participants who had missed their month 3 venipuncture visit and agreed to provide a fingerprick sample at home instead.

^jOne participant volunteered a blood sample at both months 3 and 6; however, they were only included once for the round 1 results.

^kIncludes participants who had received at least one dose of a COVID-19 vaccine. They were equally distributed among the randomization groups (Table 1; Fig. 2).

^a*N* = 1,309 with cumulative SARS-CoV-2 infections as the endpoint.

^bModeling is described in Materials and Methods and the supplemental material. In addition to the variables listed in this table, the following variables were considered for inclusion in each model: recruitment site, enrollment week, sex, smoking status, ever having tested positive for tuberculosis, current use of antidiabetes medication, and history of pulmonary disease or cardiovascular disease.

^c*N* = 1,309 with cumulative WHO-defined asymptomatic, mild, or moderate SARS-CoV-2 infections as endpoints.

^dCovariates retained in the model included age in years, hospital department, percentage of work hours with patient contact, past BCG vaccination, and current use of hypertension medication.

^e*N* = 1,309 with cumulative asymptomatic, very mild, mild, or moderate SARS-CoV-2 infections as endpoints.

^fCovariates retained in model included age in years, hospital function and department, expected to work in COVID ward, past BCG vaccination, and current use of hypertension medication.

^g*N* = 1,252 participants and *N* = 241 events with a known date; *N* = 57 events that were excluded in all survival analyses due to a lack of event date (all asymptomatic infections that were identified by serology only or insufficient data).

^hCumulative SARS-CoV-2 infection as the endpoint.

immunologically naive population. This may explain why the mean acute infection episode duration was long (15.7 days) and a substantial proportion of infected individuals developed lingering symptoms (10% long-COVID plus an additional 4% long-term loss of smell and/or taste). Studies in the United Kingdom showed that median episode duration declined as the pandemic progressed, from a median of 11 days in 2020 (25), to 8 days during Delta dominance in 2021 and 5 days during Omicron dominance in the winter of 2021–2022 (26). The proportion of COVID-19 patients developing long-COVID varied widely between studies due to differences in definitions used. A large population-based cohort in Groningen province in the Netherlands reported a prevalence of 12.7% for the period March 2020 to August 2021 using 23 symptoms, including loss of smell and/or taste, and a total symptom duration of at least 90 days after the diagnosis (27).

The percentage of participants with SARS-CoV-2 seroconversion at month 3 (7.8% versus 2.8%; *P* = 0.006), as well as mean SARS-CoV-2 anti-S1 antibody concentrations (13.1 versus 4.3 IU/mL; *P* = 0.023), were higher in the BCG group than in the placebo group, but no differences were seen at month 6 or month 12. Mean SARS-CoV-2 anti-N antibody concentrations at month 12 (not assessed at month 3 and month 6) also did not differ between randomization groups. This suggested that BCG vaccination may enhance SARS-CoV-2 antibody production after SARS-CoV-2 infection but that the effect is short-lived. This finding is not robust, because the number of participants with a SARS-CoV-2 infection in the first 3 months of the study was small and the overall anti-S1 antibody concentrations at month 3 were low. However, additional evidence for BCG potentially acting as an adjuvant comes from human challenge studies in

which participants received BCG (re)vaccination followed by influenza or COVID-19 vaccination (7, 28).

Important strengths of this trial are the large number and comprehensive nature of the endpoints. Anti-S1 antibodies are highly sensitive and specific for the presence of the SARS-CoV-2 Spike protein but are induced by both natural infection as well as COVID-19 vaccines (29, 30). Anti-N seropositivity is considered less sensitive and specific (29, 31), but it is currently the most reliable way to identify natural SARS-CoV-2 infections after COVID-19 vaccination. A recent RIVM study using the same assay that we used in this trial showed that anti-N seropositivity was 85% sensitive for mild infections and 67% sensitive for asymptomatic infections (32). While we may have missed some natural infections in the second period of the study, there were no differences between the randomization groups in the rate of COVID-19 vaccinations and proportion of participants vaccinated by the end of the study. We would therefore expect a similar number of natural infections to have been missed in each group. Additional strengths of the trial included the high diary app completion and retention rates. Furthermore, the reliability of participant-reported positive tests was high. The concordance of participant-reported positive test results with hospital laboratory data was 89% in the one hospital for which laboratory data were available (see Text S1 in the supplemental material). Negative test results, on the other hand, were substantially underreported. While these were not endpoints in any of our analyses, we did use them to rule out infection episodes potentially responsible for seroconversion. Another potential limitation was that we used two different methods of blood collection: clinician-performed venipuncture and participant-performed fingerprick sampling (33).

In conclusion, BCG vaccination of HCWs did not reduce SARS-CoV-2 infections nor infection duration or severity (on a scale from asymptomatic to moderate). In the first 3 months after vaccination, BCG vaccination may enhance SARS-CoV-2 antibody production during SARS-CoV-2 infection, but this remains to be confirmed.

MATERIALS AND METHODS

Study design and population. The BCG-Corona trial was a multicenter, double-blind, placebo-controlled randomized trial comparing BCG to placebo vaccination to prevent absenteeism and COVID-19-related endpoints. The study protocol was approved by the institutional review board of the University Medical Center (UMC) Utrecht, registered at clinicaltrials.gov (identifier NCT04328441), and published (34). The sample size was determined for the primary objective (absenteeism) by computer simulation. The primary results were also published and summarized in a supplementary text (12). Participants were doctors, nurses, paramedics, and support staff from 9 Dutch hospitals: three university hospitals that implemented in-hospital sampling (referred to as the core hospitals) and six hospitals (one university and five nonuniversity teaching hospitals) that did not. Participants were 18 years or older, were expected to be in direct contact with SARS-CoV-2-infected patients, and possessed a smartphone. The primary exclusion criteria were known allergy to BCG, active or latent *Mycobacterium tuberculosis* infection (as judged by the local Principal Investigator in each hospital), any other active infection, immunocompromised state, malignancy or lymphoma in the past 2 years, current or planned pregnancy, any vaccination in the past 4 weeks, having a hospital employment contract of less than 22 h per week, or expected work absence of at least 4 weeks.

Study procedures. After having obtained informed consent, participants were randomized to BCG or placebo (1:1) using a computer-generated dynamic randomization algorithm in random blocks of two, four, or six sequences, stratified by hospital. They received an intradermal injection in the left upper arm with either 0.1 mL of the Danish strain 1331 (Statens Serum Institut, Denmark), equivalent to 0.075 mg attenuated *Mycobacterium bovis*, or 0.1 mL of normal saline solution. Participants and study personnel conducting participant follow-up were blinded to treatment allocation. The study personnel preparing and administering the study vaccines and the data analysts were not blinded but could not influence treatment allocations or data collection.

At the randomization visit, participants completed an online baseline questionnaire (Research Online, Julius Center, UMC Utrecht, the Netherlands) and installed a diary application on their smartphone (Research Follow App, Your Research BV, Huizen, Netherlands). Participants were asked to report symptoms via the app daily, as well as SARS-CoV-2 exposures and test results and health care visits, including hospital admissions, weekly. The daily questionnaire was integrated into the weekly questionnaire after 6 months to improve user convenience, and COVID-19 vaccination questions were added after the start of the Dutch vaccination campaign on 6 January 2021. We used push notifications, e-mails, and phone calls to maximize adherence with app completion, and we terminated the app for all participants on 27 March 2021. Blood sampling continued until mid-June 2021, and we collected data on symptoms, positive SARS-CoV-2 tests, and COVID-19 vaccinations for the period between 27 March 2021 and the participant's final sampling date via an online questionnaire (Formdesk, Innovero Software Solutions BV, Wassenaar, Netherlands) and e-mail.

Blood samples were collected in two sampling rounds, dividing the follow-up time into two potential seroconversion periods. Period 1 was the period between study vaccination and the first sampling round, after about 3 months for the core hospitals and about 6 months for the other hospitals. Period 2 was the period between the first and the second sampling rounds, about 12 months after study vaccination for all hospitals. Core hospital participants donated 10 mL of serum via in-hospital venipuncture, which was processed, frozen, and transported frozen to the Dutch National Institute for Public Health and the Environment (RIVM in Dutch). The other participants, as well as core hospital participants who missed their venipuncture visit, were asked to collect about 300 μ L of peripheral capillary blood at home by fingerprick using a sampling kit that was sent to them by mail; they returned the sample by mail to the RIVM laboratory on the day of collection. The RIVM laboratory used an in-house magnetic immunoassay on a Luminex platform to determine the presence and concentrations of SARS-CoV-2-specific antibodies (Text S1) (32, 35, 36). At the end of period 1, only immunoglobulin G (IgG) antibodies against the S1 subunit of the SARS-CoV-2 Spike protein (anti-S1) were measured. At the end of period 2, both anti-S1 and IgG antibodies against the SARS-CoV-2 nucleocapsid protein (anti-N) were measured to enable differentiation between natural infections and COVID-19 vaccine-induced antibodies.

Outcome and follow-up time definitions. The presence of a SARS-CoV-2 infection was defined as a participant-reported positive test result and/or seroconversion, which in turn was defined as anti-S1 seropositivity at the end of period 1 or anti-S1 and anti-N seropositivity at the end of period 2 (Text S1). Participants with anti-N but no anti-S1 seropositivity at the end of period 2, and no corresponding positive test date, were classified as having “inconclusive episodes” and were excluded from most analyses except for some sensitivity analyses (Text S1). Participants who had less than 80% app completion without self-reported or serological evidence of an infection were also excluded because we could not be sure that they were true negatives.

Episode duration and severity were based on the diary app data (Text S1). The acute infection episode duration was defined as the number of consecutive days during which the participant reported symptoms, not including stand-alone loss of smell and/or taste or lingering symptoms (e.g., fatigue) after respiratory symptoms had ceased. Fever was defined as a temperature of 38°C or above. All other symptoms were reported on a scale of 0 to 5, with 0 for not present and 1 to 5 corresponding to increasing severity. Episode severity was categorized as asymptomatic, mild, or moderate, as defined by the World Health Organization (WHO) (37, 38). Additionally, we further subdivided the WHO-defined mild category into very mild and mild subcategories (Text S1). Separate variables were created for long-term loss of smell and/or taste and long-COVID (based on symptoms other than stand-alone loss of smell and/or taste). These were defined as continuing to report the respective symptoms for at least 60 days after the end of the acute infection episode.

The number of follow-up days was calculated as the number of days between vaccination and the first infection episode (the positive test date or the start date of the symptomatic period if no test date was available; for survival analyses) or the end of study (the month 12 sampling date or the last day of app completion if the participant did not provide a month 12 sample; for all other analyses). The app completion percentage was calculated for the period between vaccination and 27 March 2021 (Text S1).

Statistical analyses. Analyses were performed in R version 4.1.2 (PBC, Boston, MA, USA). We compared characteristics between randomization groups using the Wilcoxon rank sum test for continuous variables and chi-squared test for categorical variables. Endpoints were any SARS-CoV-2 infection or asymptomatic, mild (further subdivided into very mild and mild), or moderate infection; only the first infection per participant was included. The occurrence of endpoints in the randomization groups was modeled using (multinomial) logistic regression for cumulative incidence and Cox proportional hazards models for time to first event (the latter including infections that could be dated only). All models were first run unadjusted, followed by adjustment for potential confounders. Randomization group was forced into the multivariable models, and potential confounders were selected using a backward stepwise approach using the Akaike information criterion ($k = 2.7$) to select the final model. Sensitivity analyses were conducted assuming that the inconclusive episodes were either true episodes or not, or assuming that participants with less than 80% app completion and no reported or detected infection episode were true negatives.

Data availability. Individual participant data that underlie the results reported in this article will be made available after deidentification to investigators whose proposed use of the data has been approved by an independent review committee up to 5 years following publication. The study protocol will be available to anyone during this same time frame. Information regarding submitting proposals and accessing data may be found on <https://dataverse.nl/>.

ACKNOWLEDGMENTS

We thank the health care workers for their participation, Katina Kardaminiadis for trial management, Frank Leus and Roxanne Schaakx for data management, and all other colleagues in the participating hospitals who implemented the BCG-Corona trial, and the sample collection and testing, under difficult circumstances. The original BCG-Corona trial was not externally funded. The additional work included in this publication is part of the project “BCG vaccination to minimize COVID-19 disease severity and duration” with project number 10430 01 201 0026 of the research program COVID-19 which is financed by the Netherlands Organization for Health Research and Development (ZonMw). M.G.N. was also funded by an ERC Advanced Grant (833247) and Spinoza grant of the Netherlands Organization for Scientific Research (NWO). L.M.V. was also funded by a Wilhelmina Children’s Hospital (Utrecht) grant and a Hypatia Tenure Track grant of the Radboud University Medical Center (Nijmegen). The funders did not have any role in the collection, analysis, and interpretation of data; in the writing of the report; and in the decision to submit the paper for publication.

J.H.H.M.V.D.W., T.T.D., D.V.B., F.L.P., and M.G.N. designed and obtained funding for the study. J.H.H.M.V.D.W. supervised the data collection, analysis, and paper-writing. J.C., T.T.D., C.G., T.W.V.D.V., and A.B.J. contributed to the data collection. G.S., R.V.B., and F.V.D.K. conducted the antibody testing and D.V.B., L.M.V., and S.A.J. provided additional immunological expertise. J.C., T.T.D., C.G., and C.H.V.W. contributed to the data analyses. J.C. wrote the first draft of the manuscript. The additional members of the BCG-Corona study group contributed to the original BCG-Corona trial or other aspects of the ZonMw project (see Funding). All authors read and approved the final version. J.C. and J.H.H.M.V.D.W. had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

C.H.V.W. reports research grants from DaVolterra, bioMérieux, and LimmaTech and consultancy fees from MSD and Sanofi-Pasteur, in the last 36 months (unrelated to the work in the manuscript, payments to institution). H.L. reports a research grant from Takeda, and consultancy fees from Takeda, Sobi, Novartis, and GSK, in the last 36 months (unrelated to the work in the manuscript, payments to institution). L.M.V. reports consulting fees from MSD in the last 36 months (unrelated to the work in the manuscript, payments to institution). M.J.M.B. reports research grants from Janssen Vaccines, Novartis, CureVac, and Merck, Advisory Board memberships of Spheredyces, Pfizer, MSD, Novartis and AstraZeneca, and DSMB membership of Sanofi, in the last 36 months (unrelated to the work in the manuscript, payments to institution). M.G.N. is scientific founder and scientific advisory board member of Trained Therapeutix Discovery (TTxD) and scientific founder of Lemba Therapeutics, has obtained research grants from GSK Biologicals, TTxD, and Ono Pharma, and consultancy fees from TTxD. J.H.H.M.V.D.W. reports payments for meeting attendance from the Dutch Ministry of Health and Sports and the Netherlands Organization for Health Research and Development (ZonMw) in the last 36 months (unrelated to the work in the manuscript, payments to institution). All other authors declare no competing interests.

In addition to the writing team, the BCG-Corona study group also includes (in alphabetical order): Wim G. Boersma (NWZ Alkmaar), Özlem Bulut (Radboud), Reinout van Crevel (Radboud), Priya A. Debisarun (Radboud), Jacobien Hoogerwerf (Radboud), Marien de Jonge (Radboud), Angele P. M. Kerckhoffs (JBZ Den Bosch), Edward Knol (UMC Utrecht), Jan Pieter R. Koopman (Leiden UMC), Vincent P. Kuiper (Leiden UMC), Arief Lalmohamed (UMC Utrecht), Simone J. C. F. M. Moorlag (Radboud), Stefan Nierkens (UMC Utrecht), Cees van Nieuwkoop (HZ Den Haag), Jaap 10 Oever (Radboud), Tom H. M. Ottenhoff (Leiden UMC), Nienke Paternotte (NWZ Alkmaar), Bart J. A. Rijnders (Erasmus MC), Anna H. E. Roukens (Leiden UMC), Esther Taks (Radboud), Janetta Top (UMC Utrecht), Karin M. Veerman (Radboud), Andreas Voss (CWZ Nijmegen), and Rob Willems (UMC Utrecht).
