Chapter 4

A pre-existing coordinated inflammatory microenvironment is associated with complete response of vulvar high-grade squamous intraepithelial lesions to different forms of immunotherapy

Abstract

Immunotherapy of vulvar high-grade squamous intraepithelial lesion (vHSIL) is investigated as an alternative for surgery, because of high comorbidity and risk of recurrence. Limited evidence exists on the role and composition of the immune microenvironment in current immunotherapeutic approaches for vHSIL.

The vHSIL of 29 patients biopsied before treatment with imiquimod were analyzed by two multiplex seven-color immunofluorescence panels to investigate the pre-existing T cell and myeloid cell composition in relation to treatment response. The samples were scanned with the Vectra multispectral imaging system. Cells were automatically phenotyped and counted with inForm advanced image analysis software. Cell counts and composition were compared to that of vHSIL patients before therapeutic vaccination (n=29) and to healthy vulva (n=27).

Our data show that the immune microenvironment of complete responders (CR) to imiquimod resembled the coordinated infiltration with type 1 CD4⁺ and CD8⁺ T cells and CD14⁺ inflammatory myeloid cells also found in healthy vulva. However, more CD8⁺ T cells and FoxP3⁺ regulatory T cells were present in CR. The lesions of partial responders (PR) lacked such a coordinated response and displayed an impaired influx of CD14⁺ inflammatory myeloid cells. Importantly, complete responses after imiquimod or therapeutic vaccination showed the same dependency on a pre-existing coordinated type 1 T cell and CD14⁺ myeloid cell infiltration.

In conclusion, a good clinical outcome after two different forms of immunotherapy for vHSIL is associated with the presence of a primary inflammatory process resulting in the coordinated influx of several types of immune cells which is then amplified.

Novelty and impact: This study is the first to show that a complete clinical response of patients with vulvar high-grade squamous intraepithelial lesions is associated with a pre-existent coordinated influx of type 1 T cells and CD14⁺ myeloid cells, irrespective of the type of successful immunotherapy given (topical imiquimod therapy, therapeutic vaccination). This coordinated immune microenvironment closely resembles that of healthy vulvar tissue, suggesting that an impaired primary inflammatory process functions as immune resistance mechanism in non-complete responders.

Introduction

Vulvar High-grade Squamous Intraepithelial Lesion (vHSIL, previously known as usual Vulvar Intraepithelial Neoplasia, uVIN) is a premalignant lesion predominantly induced by high-risk Human Papilloma Virus type 16 (HPV16). The current standard of care is surgery, which is associated with high comorbidity and recurrence, or topical application of the toll like receptor 7 (TLR7) agonist imiquimod to trigger innate immune responses ^{1,2}. In addition, new approaches are being investigated, aiming at either targeting the virus, using cidofovir ¹, or by strengthening the immune system through systemic therapeutic vaccination to increase T cell reactivity against the viral oncoproteins E6 and E7. So far, complete responses have been observed in 35-46% of patients treated with imiquimod ^{1,2}, 46% of patients treated with cidofovir ¹ and 28% of vHSIL patients treated with therapeutic vaccination ³.

Imiquimod is thought to act on macrophages and dendritic cells (DCs), thereby stimulating the local production of pro-inflammatory cytokines such as IFN γ , TNF α and IL-12 which may steer the immune microenvironment towards a milieu that fosters the development of type 1 and cytolytic T cell responses (reviewed in ⁴). In addition, imiquimod may interfere with the adenosine receptor signaling pathways, alleviating local suppression and boosting the pro-inflammatory response (reviewed in ⁵). Last but not least, it may also exert a pro-apoptotic effect on tumor cells, through caspase activation ⁶. Studies on the effects of imiquimod on the immune microenvironment of vHSIL revealed imiquimod-induced consistent increases in the numbers of CD8⁺ T cells, particularly in responding vHSIL patients ^{2,7,8}. Increases in CD4⁺ T cells ⁷ and CD1a⁺ DCs ² were also reported ^{2,7}, but not confirmed ⁸. Non-responsiveness was associated with increased numbers of regulatory T cells (Tregs) after treatment ^{7,8}.

We recently used two multispectral immunofluorescence panels, one for T cells (CD3, CD8, FoxP3, Tim3, Tbet, PD-1, DAPI) and one for myeloid cells (CD14, CD33, CD68, CD11c, CD163, PD-L1, DAPI) to show that a complete regression of vHSIL after therapeutic HPV16 peptide vaccination was associated with a coordinated pre-existing pro-inflammatory immune microenvironment comprising type 1 CD4⁺ and CD8⁺ T cells and CD14⁺ inflammatory macrophages ⁹. In contrast, studies on the pre-existing immune infiltrate before imiquimod treatment showed that the numbers of vHSIL infiltrating CD4⁺ and CD8⁺ T cells as well as CD1a⁺ dendritic cells and CD68⁺ macrophages were not predictive for

responsiveness^{7,8}. In addition, while the number of pre-existing Tregs was a negative predictor in one study⁷, it was not in another⁸. Notably, most studies identified immune cells at the single marker level, and some at a double or triple marker level. This provides only limited insights in the complexity and functional status of the many different immune cells that together compose the immune microenvironment, when compared to the multispectral panels that can be used nowadays⁹.

This prompted the questions if a more in-depth study of the pre-existing immune microenvironment composition can reveal an immune profile related to response to imiquimod therapy and whether such a pre-existing immune profile in vHSIL differs from those vHSIL patients responding to therapeutic vaccination. Therefore, we studied the pre-treatment immune microenvironment of 29 vHSIL patients in relation to the clinical response after imiquimod treatment, and compared this to the pre-existing immune profile found in patients treated with a therapeutic HPV vaccine. Our data showed that a good clinical response to immunotherapy, being either imiquimod or therapeutic vaccination, is associated with a pre-existing pro-inflammatory coordinated immune microenvironment, characterized by CD14⁺ inflammatory cells, CD4⁺Tbet⁺ T cells and CD8⁺ T cells, and suggests that neither therapy is capable of overcoming an immunological cold microenvironment.

Materials and Methods

Patient samples

Pre-treatment formalin-fixed paraffin-embedded (FFPE) biopsies of 29 women of ≥ 18 years old with histologically confirmed vHSIL were retrospectively included. Patient samples were collected from two hospitals in the Netherlands: the Leiden University Medical Center (LUMC, Leiden, The Netherlands), and the Haga Hospital (the Hague, The Netherlands). Clinical complete response (CR, n=14) upon therapy was defined as 100% lesion clearance, partial response (PR, n=12) as $\geq 50\%$ lesion clearance, and no response (NR, n=3) as $< 50\%$ lesion regression. Moreover, FFPE healthy HPV-negative vulvar tissue from 27 anonymized women who underwent labia reduction surgery was included.

Multiplex immunofluorescence imaging

Two seven-color multispectral immunofluorescence panels were applied, one for T cells, consisting of CD3, CD8, FoxP3, Tim3, Tbet, PD-1, DAPI, and

one for myeloid cells, consisting of CD14, CD33, CD68, CD11c, CD163, PD-L1, DAPI, as previously published in ⁹. In these panels a combination of direct detection (primary antibody directly labelled with fluorochrome) and indirect detection (fluorochrome labelled secondary antibody) of markers was used ¹⁰, and dim markers (PD-L1, PD-1 and Tbet) were tyramide signal amplified with Opal (PerkinElmer) to enable their detection by fluorescence microscopy. This combination of different marker detection methods, fully optimized for each marker, enabled the selection of the best primary antibodies without being restricted by clashing isotypes and species. Antibody specificity was first assessed with immunohistochemistry and monoplex immunofluorescence, tonsil slides serving as positive control, and subsequently the immunofluorescence detection conditions for each marker in multiplex immunofluorescence were optimized. A frequently encountered problem in multiplex immunofluorescence is spectral overlap between signals. To overcome this, we designed our panels in such a way that markers with an equally strong signal intensity were put in the same microscope detection filter, we alternated nuclear and membranous markers in the light spectrum when possible, and finally we found that alternating secondary Alexa fluorochromes (ThermoFisher Scientific) with CF dyes (Biotium) when spectral overlap between two consecutive Alexa fluorochromes was detected despite the minimal exposure times used, resolved the cross bleed of signal successfully. An overview of the antibodies and staining methods included in each panel are shown in **Supplemental Table 1**. In short, 4µm FFPE tissue sections were deparaffinized, endogenous peroxidase was blocked with hydrogen peroxide and heat induced epitope retrieval was performed in the T cell panel with citrate (10mM, pH 6.0) and in the myeloid cell panel with tris-EDTA (10mM/1mM, pH 9.0). SuperBlock (ThermoFisher Scientific) was used to block non-specific binding sites. First, the antibodies detected by Opal were applied, followed by the unconjugated antibodies which incubated overnight. On the second day, after binding of the previous with their corresponding fluorescently labelled secondary antibodies, the directly labeled primary antibodies were incubated for 5 hours, and lastly DAPI was applied as nuclear counterstain ⁹.

Quantification of immune cells in the TME

As published in ⁹, immunofluorescence images of the entire tissue sections were acquired with the Vectra 3.0.5 multispectral imaging microscope (PerkinElmer) at 20x magnification. Immune cells in the TME were automatically phenotyped and counted with inForm 2.4 image analysis software (PerkinElmer) after manual training. The software was trained to segment epithelium and stroma, segment

DAPI+ nucleated cells, and assign a phenotype to each cell. All phenotypes were visually inspected on accurateness, and if errors were detected the training was further optimized until all discrepancies were resolved. Given the multitude of possible co-expressed markers and the limited trainability of the inForm software in reliably detecting complex multi-marker expressing cell phenotypes, each seven-color panel was divided into multiple sub-analyses that contained a small number of markers which the inForm software could robustly identify (**Supplemental Table 2**). The phenotypes of all sub-analyses were merged per cell based on its X,Y-positions with an R script, which enabled the description of the full seven marker expression profile for each cell. Immune cell counts were normalized for tissue size (cells/mm² epithelium and cells/mm² stroma). After merging the sub-analyses, a threshold of a median cell count ≥ 10 cells/mm² in at least one group (NR, PR, CR or healthy vulva) was applied to study the changes in biologically common phenotypes.

Statistical analysis

Statistical data analysis was performed with SPSS 25.0 (IBM Corporation). The median immune counts of the different groups (PR, CR and healthy vulva) were compared with the non-parametric Mann-Whitney U test. NRs were not included in the statistical analyses due to their small sample size (n=3). Pearson correlation was used to study correlations between the T cell infiltrate and the myeloid cell infiltrate in each group. Two sided p-values < 0.05 were marked as significant. GraphPad Prism 8.0.1 (GraphPad Software Inc.) was used to create graphs.

Results

The pre-treatment immune microenvironment reveals high heterogeneity between vHSIL patients.

We analyzed the complexity of the vHSIL-infiltrating T cell and myeloid cell populations in 29 patients (**Table 1**), before topical imiquimod treatment, using two seven-color multiplex immunofluorescence panels (**Supplemental Tables 1,2**). Analyses of these images stained for T cells and myeloid cells (**Figure 1; Supplemental Figures 1,2,3**) revealed 6 different phenotypes of T cells and 8 different phenotypes of myeloid cells (**Figure 2A**). The CD3⁺CD8⁻ T cells detected were designated as CD4⁺ T cells, based on our earlier study showing that on average 99% of the CD3⁺CD8⁻ T cells were CD4⁺ T cells ⁹. Moreover, it showed that the vHSIL patients formed a heterogeneous group with high inter-patient variability in the numbers of intraepithelial and stromal immune cells (**Figure 2A; Supplemental Table 3**).

Figure 1. Multiplex immunofluorescence to detect T cells and myeloid cells in vHSIL.

Figure 2. The pre-imiquimod TME differs between the different response groups.

A) The numbers of intraepithelial and stromal infiltrating T cell and myeloid cell subtypes are presented as cells/mm² epithelium and cells/mm² stroma in the pre-imiquimod vHSIL biopsies of 29 patients. Each dot represents an individual sample, the horizontal bars indicate the median cell counts, the vertical bars are

the 95% confidence intervals. The **B)** T cell and **C)** myeloid cell infiltrate of the pre-imiquimod vHSIL patients when grouped according to response (PR, CR), and compared to healthy vulvar tissue (n=27), presented as median cells/mm² epithelium and median cells/mm² stroma. A threshold of a median cell count ≥ 10 cells/mm² in at least one group (NR, PR, CR or healthy vulva) was applied to study the changes in biologically common phenotypes. CR=complete responders (n=14); PR=partial responders (n=12).

Differences in the myeloid cell compartment of vHSIL correlate with response to imiquimod.

The vulva is a highly immune active anatomical location as shown by the high numbers of T cells and myeloid cells infiltrating this healthy tissue (**Figure 2**). To study if quantitative or qualitative differences in immune infiltrate were associated with a different clinical outcome in vHSIL, we grouped the patients by clinical response (PR, CR) and compared them to healthy tissue. This revealed that while the PR and CR patients displayed abundant T cell infiltration in the stroma, with higher numbers of CD8⁺ T cells and CD3⁺CD8⁺FoxP3⁺ Tregs, the intraepithelial T cell infiltration was considerably reduced as compared to healthy tissue, lacking CD3⁺CD8⁺PD1⁺/Tbet⁺ activated type 1 T helper cells in particular (**Figure 2B**; **Supplemental Table 3**). No overt differences in T cell infiltration existed between the PR and CR patients (**Figure 2B**; **Supplemental Table 3**). The myeloid cell population differed the most among the different clinical groups. There was substantial intraepithelial and stromal infiltration by CD33⁺ immature myeloid cells (**Figure 2C**; **Supplemental Table 3**), which most likely are myeloid derived suppressor cells (MDSC) based on our earlier studies ¹¹, but their numbers didn't differ between the groups. Furthermore, a substantial fraction of the myeloid cells in the stroma comprised different populations of CD14⁺ inflammatory myeloid cells, in particular CD14⁺CD68⁺CD163⁺ cells and CD14⁺CD68⁺CD163⁺ M2 macrophages. Whereas the numbers of the different stromal CD14⁺ inflammatory myeloid cell subpopulations between healthy vulva and CR lesions didn't differ much, the numbers of these myeloid cell subpopulations were significantly lower in the lesions of PR patients (**Figure 2C**; **Supplemental Table 3**). Finally, the number of stromal CD11c⁺ DCs was slightly increased in vHSIL when compared to healthy vulva.

Thus while the numbers and composition of infiltrating immune cells of CR patients most closely resembled that of healthy vulva, PR patients showed impaired infiltration with inflammatory myeloid cells (**Figure 2**).

The composition of the vHSIL immune microenvironment in complete responders fits best with the mode of action of the chosen immunotherapeutic treatment.

The correlation between a CR after imiquimod and a pre-existent high infiltration of the lesions with CD4⁺Tbet⁺ T cells and CD14⁺ inflammatory myeloid cells (**Figure 2**) as well as a coordinated overall immune cell infiltration (**Figure 3**) was also observed by us in vHSIL patients treated with a therapeutic vaccine containing synthetic long peptides of HPV16 E6 and E7 oncoproteins⁹. This suggests that the immune composition of the lesions of CR patients is highly similar irrespective of the immunotherapeutic treatment. We, therefore, compared the composition of the stromal T cell and myeloid cell compartment in both groups of treated patients. Interestingly, the composition of the T cell fractions didn't overtly differ between the groups of patients with a different clinical outcome after imiquimod treatment (**Figure 4A**), whereas this was clearly the case between the groups of patients treated with a therapeutic vaccine (**Figure 4B**). Interestingly, the myeloid cell composition didn't differ much between the therapeutically vaccinated patient response groups, contrary to the different response groups to topical imiquimod treatment. In the latter, patients with a PR or CR had a considerably different myeloid cell composition compared to NR patients (**Figure 4**), implying that for response to imiquimod the number and composition of vHSIL infiltrating myeloid cells is of importance. Thus, whereas the composition of the T cell compartment was important for the outcome of a therapy aiming to improve the T cell response by therapeutic vaccination, the numbers of CD14⁺ cells in the myeloid cell compartment were more important for response to a treatment with topical imiquimod, known to stimulate myeloid cells⁴ and CD14⁺ cells in particular¹³ (**Figure 5**).

Figure 4. Fractional differences between the pre-imiquimod and pre-vaccination immune microenvironment in vHSIL, divided based on clinical response to the respective therapy.

A) Fractional composition of the T cells and myeloid cells in the pre-imiquimod vHSIL cohort, grouped according to response (NR n=3, PR n=12, CR n=14), and compared to healthy vulva (n=27). **B)** Fractional composition of the T cells and myeloid cells in the pre-therapeutic vaccination vHSIL cohort, grouped according to response (NR n=12, PR n=10, CR n=7), and compared to healthy vulva (n=27).

Figure 5. Summary of complete responder's vHSIL immune microenvironment in the context of the mode of action of imiquimod and therapeutic vaccination.

The vHSIL immune microenvironment of complete responders to imiquimod and therapeutic HPV16 synthetic long peptide (SLP) vaccination comprises a coordinated infiltration with type 1 (Tbet⁺) CD4⁺ and CD8⁺ T cells as well as CD14⁺ inflammatory myeloid cells. Imiquimod stimulates CD14⁺ myeloid cells to produce pro-inflammatory cytokines which activate and attract the type 1 T cells¹³. Whereas, therapeutic vaccination stimulates the type 1 T cell response, which in turn produces cytokines that also stimulate the influx of the lesion by CD14⁺ myeloid cells⁹. This figure was created using adapted images of Servier Medical Art, licensed under a creative commons attribution 3.0 unported license.

Discussion

Here we show that a complete regression of vHSIL after imiquimod treatment is associated with a pre-existing well-coordinated overall infiltration between T cells and myeloid cells, and in particular the influx of vast numbers of vHSIL-infiltrating type 1 T cells and CD14⁺ inflammatory myeloid cells. Healthy vulva is richly infiltrated and guarded by pro-inflammatory T cells and myeloid cells. While the immune cell infiltration in the group of patients with a CR didn't differ much from healthy vulva, the myeloid cell infiltration of lesions from PR patients was significantly lower than in healthy vulva. This was also visualized by the clear disconnection between the infiltration with CD8⁺ T cells and myeloid cells in the group of patients with a PR. The requirement for an ongoing T cell response for imiquimod to be effective was also previously reported ¹⁴ but here it is shown that also a strong influx with CD14⁺ myeloid cells should be maintained. This would be in line with the mode of action of imiquimod which is acting predominantly on CD14⁺ cells ¹³, the activation of which leads to the increased infiltration of several types of adaptive immune cells ^{2, 7, 8}. The presence of these CD14⁺ cells at lower numbers and in an unfavorable balance with suppressive immune cells (M2 macrophages, MDSC) may serve as a primary resistance mechanism to imiquimod treatment.

In our recent study on the immune microenvironment of vHSIL completely regressing after therapeutic vaccination, we also found a well-coordinated immune infiltration in CR patients, and a positive association between clinical efficacy and high numbers of vHSIL-infiltrating type 1 T cells and CD14⁺ inflammatory myeloid cells. Moreover, the vHSIL that led to a PR after vaccination displayed a disconnection between CD8⁺ T cell and myeloid cell infiltration ⁹. However, as shown in the current study the clinical outcome after therapeutic vaccination was more related to differences in the composition of the CD4⁺ T cell fraction, fitting with the mode of action of this vaccine ^{3, 15-17}.

The combination of these two data sets leads to the conclusion that both a coordinated inflammatory immune response comprising type 1 CD4⁺ and CD8⁺ T cells, as well as CD14⁺ myeloid cells are potentially required for optimal immune control and clearance of vHSIL. Previously, it has been demonstrated that the rejection of human tissues (tumors, allografts, autoimmune flares) is associated with an almost identical modular signature and defined as the immunological constant of rejection (ICR) ^{18, 19}. In the context of our observations that complete rejections of vHSIL are associated with the presence of vast

numbers of type 1 T cells and CD14⁺CD68⁺CD163⁺ myeloid cells, it is of interest to know that the ICR is a process that begins with the induction of a primary inflammatory process leading to the chronic infiltration of monocytes and other cells related to innate immune mechanisms but lack effector function. The presence of pro-inflammatory signals such as IFN γ , which is likely to come from the Tbet⁺ T cells in vHSIL, induce the activation of monocytes, which in turn, may start to produce pro-inflammatory cytokines such as IL-12, IL-15, and IL-18, important cytokines to drive and sustain the type 1 immune response required for rejection^{18,19}. Thus, it seems that both imiquimod and therapeutic vaccination will lead to complete rejections when the process of the ICR is already ongoing.

Following this line of reasoning, it also implies that none of the two immunotherapeutic approaches is able to breakdown the barrier existing in cold lesions. We have shown that this is true for therapeutic vaccination⁹. It is likely that this barrier is induced by the infection with HPV as healthy vulva tissue is strongly infiltrated with immune cells. So what could underlie an impaired primary process of inflammation? We and others have shown that HPV exploits several mechanisms to suppress the primary inflammatory process²⁰⁻²². In addition genomic instability in these lesions²³⁻²⁵ may turn these lesions cold. In such cases, vHSIL lesions are better treated with cidofovir based on the fact that cidofovir and imiquimod were reported to be effective in two distinct biologically defined vHSIL groups, reflected by their HPV E2 DNA methylation status²⁶.

Our study shows the benefits of using multispectral imaging in order to obtain a profile of the immune microenvironment, which are correlated to the success or failure of an immunotherapeutic treatment. While previous studies^{2,7,8} were unable to find a relation between the numbers of immune infiltrating T cells or myeloid cells and clinical outcome, this was now possible because additional markers allowed for a better definition of the different subpopulations, some of which were correlated with the response to imiquimod or therapeutic vaccination. For future studies, it would be of interest to study the post-imiquimod immune microenvironment because the imiquimod-induced changes in the different subsets of immune cells will increase our knowledge on what is exactly required for an effective immune control of HPV-induced lesions.

CD14-CD68-CD163-CD11c+	-	-	-	-	2.55 (0-6.12)	6.63 (1.44-11.53)	5.26 (0.99-12.07)	0.95 (0.27-4.71)	PR*H, CR*H	

Non-responders (NR, n=3), partial responders (PR, n=12), complete responders (CR, n=14) and healthy vulva (H, n=27). A threshold of a median cell count of ≥ 10 cells/mm2 per tissue compartment was applied, to only select relevant phenotypes for analyses. NRs have not been included in the statistical analyses, due to their small sample size. Differences between two groups were calculated with a Mann-Whitney test, statistical significance is indicated with asterisks: * $p<0.05$, ** $p<0.01$, *** $p<0.001$ and **** $p<0.0001$.
