Abstract

We study how environment regulates the star formation cycle of 33 Virgo Cluster satellite galaxies on 720 pc scales. We present the resolved star-forming main sequence for cluster galaxies, dividing the sample based on their global H I properties and comparing to a control sample of field galaxies. H I–poor cluster galaxies have reduced star formation rate (SFR) surface densities with respect to both H I–normal cluster and field galaxies (~ 0.5 dex), suggesting that mechanisms regulating the global H I content are responsible for quenching local star formation. We demonstrate that the observed quenching in H I–poor galaxies is caused by environmental processes such as ram pressure stripping (RPS), simultaneously reducing the molecular gas surface density and star formation efficiency (SFE) compared to regions in H I–normal systems (by 0.38 and 0.22 dex, respectively). We observe systematically elevated SFRs that are driven by increased molecular gas surface densities at fixed stellar mass surface density in the outskirts of early stage RPS galaxies, while SFE remains unchanged with respect to the field sample. We quantify how RPS and starvation affect the star formation cycle of inner and outer galaxy disks as they are processed by the cluster. We show both are effective quenching mechanisms, with the key difference being that RPS acts upon the galaxy outskirts while starvation regulates the star formation cycle throughout disk, including within the truncation radius. For both processes, the quenching is caused by a simultaneous reduction in the molecular gas surface densities and SFE at fixed stellar mass surface density.

1. Introduction

Understanding the gas–star formation cycle in galaxy clusters has been an active area of research for more than four decades (see the reviews by Haynes et al. 1984; Boselli & Gavazzi 2006, 2014; Cortese et al. 2021; Alberts & Noble 2022; Boselli et al. 2022, and references therein). It is now clear that there are a large number of environmental processes that affect

how star formation proceeds in cluster satellite galaxies, often concurrently (e.g., starvation—Larson et al. 1980; tidal stripping—Moore et al. 1999; thermal evaporation—Cowie & Songaila 1977; and gravitational interactions—Moore et al. 1996). A common attribute of these mechanisms is that they primarily exert their influence on galaxy evolution by perturbing the interstellar medium (ISM).

Atomic hydrogen gas (H I) is usually the most massive and extended component of the ISM, extending well beyond the galaxy stellar radius (Cayatte et al. 1994), making it an excellent tracer of the environmental influence on galaxies. As such, and given the efficiency with which H I reservoirs can be mapped, a large number of studies have confirmed the systematic depletion of H I reservoirs by external mechanisms (e.g., Giovanelli & Haynes 1985; Solanes et al. 2001; Gavazzi

et al. 2008; Chung et al. 2009; Cortese et al. 2011; Serra et al. 2012; Catinella et al. 2013; Brown et al. 2017; Stevens & Brown 2017; Stevens & Diemer 2019; Healy et al. 2021).

Although less well studied than H I, there is a growing body of work revealing the role of environment in perturbing galaxies' molecular gas content, as the direct fuel for star formation (Boselli et al. 2002; Fumagalli et al. 2009; Wilson et al. 2009; Corbelli et al. 2012; Boselli et al. 2014; Mok et al. 2016; Nehlig et al. 2016; Lee et al. 2017; Moretti et al. 2018; Jáchym et al. 2019; Zabel et al. 2019; Moretti et al. 2020a, 2020b; Cramer et al. 2020; Brown et al. 2021; Stevens et al. 2021; Lee et al. 2022; Morokuma-Matsui et al. 2022; Roberts et al. 2022).

Recent years have seen a particular focus on the role of ram pressure stripping (RPS) in both quenching and inducing star formation in cluster galaxies. RPS occurs in galaxies moving at high velocity through the intracluster medium (ICM), where pressure exerted on the ISM is strong enough to remove gas from the disk directly. First proposed by Gunn & Gott (1972), there are now many examples of this mechanism affecting how galaxies evolve in dense environments (e.g., Abadi et al. 1999; Hester 2006; Fumagalli et al. 2014; Fossati et al. 2016; Poggianti et al. 2017; Roberts et al. 2021). Indeed, this topic has been the subject of two recent review papers, Cortese et al. (2021) and Boselli et al. (2022), and we refer the interested reader to those works for a comprehensive overview.

There is clear evidence that RPS is capable of quenching satellite galaxies, primarily through removal of molecular gas and/or suppression of the star formation efficiency (SFE) throughout the disk (e.g., Mok et al. 2017; Moretti et al. 2018; Zabel et al. 2020; Villanueva et al. 2022; Zabel et al. 2022). However, there are also a growing number of studies showing elevated star formation in galaxies that are actively undergoing stripping, suggesting that the pressure at the ICM–ISM interface acts to increase the SFE or aid the conversion of H I into molecular gas (e.g., Ebeling et al. 2014; Nehlig et al. 2016; Vulcani et al. 2018; Moretti et al. 2020a, 2020b; Lizée et al. 2021; Roberts et al. 2022).

The lack of widespread rejuvenation of star formation in cluster galaxies means that starvation—the cessation of gas supply to the ISM—must also be an important regulatory mechanism in this environment. Indeed, the prevalence of starvation is also inferred by studies of slow quenching timescales in cluster galaxies (e.g., McGee et al. 2009; Haines et al. 2015; Paccagnella et al. 2016). For cluster galaxies, especially those that have undertaken one pericenter passage or more, it is highly likely that both starvation and direct gas stripping are playing a major role in the gas–star formation cycle. For such systems, we can therefore more clearly define the term starvation to mean the lack of gas accretion after parts of the disk have been stripped. Thus, the key questions are not if but how, where, and when do RPS and starvation affect the star formation cycle? Answering these requires establishing if the remaining gas reservoirs of stripped galaxies are affected by other environmental processes such as starvation, or if they proceed to form stars as though they were in the field. In other words, does the starvation mechanism itself break the star formation cycle, or does it simply stop it from starting again once it has been disrupted by another process?

The combined literature has led to a general consensus that environmental processes play an important role in regulating star formation in dense environments. However, the exact

nature of different galaxy quenching mechanisms, and the extent to which they influence molecular gas content and SFE are questions that are still unanswered.

It is now common to use a measurement of H I deficiency as a proxy for environmental influence. This parameter quantifies the H I content with respect to the typical content of a comparable field galaxy. Most commonly, field control samples are constructed to match the target galaxy in either the size or mass of the stellar disk (Haynes & Giovanelli 1984; Chung et al. 2009; Boselli et al. 2014; Zabel et al. 2022). There are a number of studies demonstrating the efficacy of H I deficiency as a tracer of environmental influence, both for cluster galaxies in general (e.g., Boselli & Gavazzi 2009; Li et al. 2020) and the specific galaxies studied in this work (e.g., Yoon et al. 2017; Zabel et al. 2022; Watts et al. 2023). For an extensive discussion of H I deficiency, including the respective merits of the various definitions, we refer the reader to Section 3 of Cortese et al. (2021).

In nearby galaxies, studying the form and scatter of the spatially resolved star-forming main sequence (rSFMS), which relates the stellar mass surface density, Σ_* , with the star formation rate (SFR) surface density, Σ_{SFR} , is an increasingly common approach to characterize the local star formation cycle. To first order, how regions evolve along and deviate from this relationship is determined by the processes that regulate the conversion of gas into stars (Sánchez et al. 2013; Cano-Díaz et al. 2016; Hsieh et al. 2017; Lin et al. 2019; Vulcani 2019; Ellison et al. 2020; Enia et al. 2020; Sánchez 2020; Vulcani 2020; Ellison et al. 2021; Baker et al. 2022; Bluck et al. 2022). Recent works investigating the rSFMS in field galaxies on kiloparsec spatial scales present a picture where star formation is regulated locally (e.g., feedback or self-regulation) while quenching is more closely related to global mechanisms that affect the total gas reservoir (Bluck et al. 2020; Ellison et al. 2020; Sánchez 2020). Thus, considering the cluster rSFMS is important for establishing how environmental mechanisms which affect the global H I content (as measured by H I deficiency) are capable of either inducing or quenching local star formation activity. Studying the resolved relation rather than the global SFR–stellar mass relationship also allows one to identify the signatures of environmental quenching in different parts of the galaxy disk more readily (e.g., inner disk versus outskirts, leading versus trailing edge, etc.).

Since cold molecular gas is the raw fuel for star formation (e.g., Bigiel et al. 2008), the relation between Σ_* and Σ_{SFR} (i.e., the rSFMS) can be understood as a consequence of the more fundamental connections between these two properties and the molecular gas surface density, Σ_{mol} (Lin et al. 2019; Pessa et al. 2021; Sánchez et al. 2021).

The connection between the SFR and molecular gas surface densities is commonly known as the resolved Kennicutt–Schmidt relation (rKSR) and has been studied extensively in nearby field galaxies (e.g., Bigiel et al. 2008; Leroy et al. 2013; Roychowdhury et al. 2015; Morselli et al. 2020). Recent resolved studies of molecular gas in cluster galaxies have begun to explore the subkiloparsec rKSR in this regime for statistically significant samples (Zabel et al. 2020; Jiménez-Donaire et al. 2023). These studies show that, despite the large galaxy-to-galaxy variations, the cluster rKSR largely follows the same form as in field galaxies. However, Jiménez-Donaire et al. (2023) also demonstrate that environmental mechanisms

that affect the galaxy HI content reduce the SFE of the molecular gas.

Although less well studied than the rKSR, a growing number of works have established a correlation between molecular gas and stellar surface densities—known as the resolved molecular gas main sequence (rMGMS)—which governs the amount of gas available for star formation (Lin et al. 2019; Morselli et al. 2020; Ellison et al. 2021; Pessa et al. 2021). The presence of the rMGMS in cluster members was recently established by Watts et al. (2023) who show that the individual cluster galaxy rMGMS gradually moves below the field relation as HI deficiency increases.

Recent field galaxy studies have analyzed connections between the rSFMS, rMGMS, and rKSR simultaneously for several different samples (e.g., Lin et al. 2019; Ellison et al. 2020; Pessa et al. 2021; Sánchez et al. 2021; Baker et al. 2022). Ellison et al. (2020) and Baker et al. (2022) demonstrate that the rSFMS in field galaxies is driven primarily by the form and scatter of the rKSR (i.e., SFE). A secondary but strong correlation with the rMGMS (i.e., gas content) is likely a consequence of the rKSR’s slightly sublinear nature in log–log space (Ellison et al. 2021; Sánchez et al. 2021; Jiménez-Donaire et al. 2023). Since the rSFMS is fundamentally a projection of the rMGMS and rKSR, it is critical to interpret this relation in the context of the other two. In taking this approach, the aim of this work is to provide a holistic view of how different environmental mechanisms regulate star formation activity in the VERTICO sample.

The paper is structured as follows. Section 2 describes the data and sample selection. We present evidence for the influence of environmental processes on the molecular gas–star formation cycle of Virgo galaxies in Section 3. Section 4 discusses these results and our interpretation in the context of previous work. Lastly, we summarize our findings and briefly highlight areas for future research in Section 4. Throughout this analysis, we assume a constant distance of 16.5 Mpc to all Virgo galaxies based upon the Virgo Cluster distance found by Mei et al. (2007). SFRs and stellar masses are derived assuming a Chabrier initial mass function (Chabrier 2003).

2. Data

The data in this paper are drawn from two surveys of nearby star-forming galaxies. Our primary analysis sample of cluster galaxies is selected from the Virgo Environment Traced in CO survey (VERTICO; Brown et al. 2021) while our field control sample is selected from the Heterodyne Receiver Array CO Line Extra-galactic Survey (HERACLES; Leroy et al. 2009). This section describes the data from each.

2.1. The VERTICO Survey

VERTICO is a completed Atacama Large Millimeter/submillimeter Array (ALMA) Cycle 7 Large Program that uses ALMA’s Morita array to map the distribution and kinematics of CO(2–1) across 51 Virgo Cluster galaxies on subkiloparsec scales. Here we briefly describe the VERTICO sample, CO(2–1) data products, and derivation of the molecular gas surface densities. For more details, we refer the reader to Brown et al. (2021). From here on, we use “CO” to explicitly refer to the CO(2–1) transition. Other transitions are noted accordingly.

All resolved data used in this work are smoothed to the smallest common beam diameter of 9'' with a pixel scale of 4''. The 9'' beam corresponds to a physical size of 720 pc at the distance of Virgo (16.5 Mpc, $1'' \approx 80$ pc; Mei et al. 2007). Matching the beam size across all galaxies ensures that each resolution element covers approximately the same physical area of the disk, and the approximate Nyquist sampling with the pixel scale reduces the effect of beam oversampling contributing to trends in our analysis. Given the consistent physical scale of each pixel, we use the words “pixel” and “region” interchangeably to improve readability.

The molecular gas surface density maps, in units of solar masses per square parsec, are derived assuming a constant CO(1–0) conversion factor of $\alpha_{\text{CO}} = 4.35 M_{\odot} \text{ pc}^{-2} (\text{K km s}^{-1})^{-1}$ and CO(1–0)-to-CO(2–1) line luminosity ratio (R_{21}) of 0.8 (Brown et al. 2021). These maps include the 36% contribution of helium in addition to H₂ and are corrected for projection effects using the optical *r*-band inclination.

From the VERTICO sample of 49 galaxies detected in CO, we selected all galaxies with an optical *r*-band inclination $\leq 80^\circ$ and pixels with a signal-to-noise ratio ≥ 2 . Further, we remove the three lowest stellar mass galaxies in our sample (NGC 4299, NGC 4532, and NGC 4561) since these galaxies have low metallicity and their molecular gas component is likely underestimated by the constant α_{CO} used in this paper. We also exclude NGC 4321 from our sample as the resolving beam of the ACA CO data is $\approx 10''$. This selection yields a final sample of 15,401 pixels drawn from 33 galaxies covering a range in projected cluster-centric distances between $\sim 0.2 r_{200}$ and $\sim 2.5 r_{200}$ ($r_{200} = 1.55$ Mpc; McLaughlin 1999; Brown et al. 2021).

2.2. HERACLES

HERACLES is a survey of CO(2–1) emission in 48 nearby field galaxies ($2 < D(\text{Mpc}) < 25$) spanning a comparable range in global stellar mass and specific star formation rate (sSFR) to VERTICO ($10^{8.5} < M_*(M_{\odot}) < 10^{11}$ and $10^{-11.5} < \text{sSFR}(\text{yr}^{-1}) < 10^{-9.2}$, respectively). The survey’s public data cubes have an angular beam diameter of 13'' in 5 km s^{−1} wide channels. We refer the reader to Leroy et al. (2009) for further details on the survey design and data products.

The HERACLES targets span a range of distances so the physical scales probed by the data’s common 13'' beam varies considerably. Therefore, for the comparison to VERTICO, we select the 10 closest galaxies ($2.9 \leq D(\text{Mpc}) \leq 10.6$) and convolve the cubes with a Gaussian kernel so that the final beam matches the 720 pc physical resolution of the VERTICO 9'' beam. This ensures we are probing the same physical scales with our comparison. We also smooth the data to the same 10 km s^{−1} velocity resolution as the final VERTICO data cubes. Science ready data products such as flux, gas surface density, and signal-to-noise maps are produced using an identical procedure to the VERTICO data products described in Brown et al. (2021). For this work we apply the selection criteria described in Section 2.1, yielding a final field control sample of 10,817 pixels from drawn from 10 HERACLES survey galaxies.

2.3. Stellar Mass and SFR Surface Densities

This section briefly describes the production of 9'' SFR and stellar mass surface density maps for both the VERTICO and HERACLES galaxies. A fuller description of this procedure

Figure 1. Comparison of the resolved physical property distributions for the VERTICO cluster (blue) and HERACLES field (gray) samples. From left to right: molecular gas surface density (Σ_{mol}), stellar surface density (Σ_*), SFR surface density (Σ_{SFR}), and sSFR. All surface density properties are corrected for projection effects using the optical inclinations. As the cluster sample, regions in VERTICO galaxies are skewed to lower molecular gas and SFR densities.

can be found in Jiménez-Donaire et al. (2023) and Villanueva et al. (2022) for the SFR and stellar mass surface density maps, respectively.

All maps are constructed using Galaxy Evolution Explorer (GALEX) and Wide-field Infrared Survey Explorer (WISE) photometry following the procedure laid out in Leroy et al. (2019). The final $9''$ resolutions match the beam size of the VERTICO CO products. SFR surface density maps are constructed from a combination of GALEX near-ultraviolet (NUV) and WISE3 photometry at $9''$. We are required to use WISE3 as our obscured tracer at $9''$ resolution as the WISE4 beam is too coarse. Stellar mass surface density maps are derived from WISE1 photometry. We determine the local mass-to-light ratio (at $3.4 \mu\text{m}$) using the WISE3-to-WISE1 color as an sSFR-like proxy and following the calibrations in Leroy et al. (2019). The WISE1 images are then combined with the derived mass-to-light ratios to produce stellar mass surface density maps. As with the molecular gas, the stellar and SFR surface densities are corrected for inclination effects by a factor of $\cos(i)$.

Figure 1 shows the distributions of the resolved physical properties for the 15,401 pixels in the VERTICO analysis sample and 10,817 pixels in the HERACLES field control sample. From left to right, the properties shown are the molecular gas surface density (Σ_{mol}), stellar surface density (Σ_*), SFR surface density (Σ_{SFR}), and sSFR ($=\Sigma_{\text{SFR}}/\Sigma_*$). The distribution of pixels belonging to the VERTICO cluster galaxy sample extend to slightly lower molecular gas surface and SFR surface densities. There is an excess in cluster pixels above $\Sigma_* \sim 10^8 M_\odot \text{kpc}^{-2}$ with respect to the field sample, although the shapes of the distributions are similar, which may be driven by an excess in central stellar features such as bars and bulges in VERTICO. The combination of lower SFRs and high stellar surface densities results in the significant skew of the VERTICO pixels to lower sSFRs. The next section explores whether the differences between the field and cluster samples are the result of environmental processes or internal secular evolution or a mix of both.

3. Results

In this section, we present the VERTICO rSFMS—the first such characterization of this relationship for cluster galaxies—and study the VERTICO rMGMS and rKSR first published in Watts et al. (2023) and Jiménez-Donaire et al. (2023), respectively.

H I deficiency values for the VERTICO cluster galaxies are adopted from Chung et al. (2009), who compare their H I content with field galaxies of the same optical size, independent of morphological type. We divide the VERTICO sample described in Section 2 into two subsamples based on global galaxy H I deficiency: the H I-poor subsample contains pixels belonging to galaxies with $\text{H I-def} \geq 0.5$ (6448 pixels, 16 galaxies) while the H I-normal subsample contains pixels drawn from galaxies with $\text{H I-def} < 0.5$ (8953 pixels, 17 galaxies). The upper-left panel in Figure 2 shows this selection in the distribution of H I deficiencies for the 33 VERTICO galaxies studied in this work.

3.1. The VERTICO rSFMS, rMGMS, and rKSR

The rSFMS, rMGMS, and rKSR for the VERTICO H I-normal (blue) and H I-poor (red) subsamples as well as the HERACLES field sample (gray) are shown in the top-left, bottom-left, and bottom-right panels of Figure 2, respectively. The corresponding best-fit relations for the H I-normal and H I-poor subsamples are shown by the solid lines in each plot. The fits are calculated using the LTSFIT Python package described in Cappellari et al. (2013, their Section 3.2) which accounts for measurement uncertainties in both axes to determine the best-fit parameters and scatter. The fit parameters for each relation are provided in the Appendix.

The rSFMS (top right) and rMGMS (bottom left) in the H I-normal cluster galaxies closely follow the field relations although there is a small deviation to lower gas densities at low stellar mass density in the rMGMS. This shows that where there is little effect on the H I content, the influence of environment on the molecular gas and subsequent star formation activity is also minimal. The rMGMS offset at the lowest stellar densities may be an indicator of environmental effects beginning to take hold in the galaxy outskirts and we return to this point with Figure 5. On the other hand, the H I-poor galaxies are clearly offset to lower molecular gas and SFR densities at fixed stellar density with respect to the field relations. Thus, in galaxies where the global H I content is reduced with respect to the field, there is also a significant reduction in the molecular densities and, consequently, star formation activity.

The best-fit rSFMS relation for H I-poor galaxies is 0.62 dex below the H I-normal relation, demonstrating that the processes that are reducing the global H I content are also responsible for quenching star formation within the truncation radius (Watts et al. 2023) and on the scale of individual pixels ($\sim 720 \text{ pc}$).

Figure 2. The effect of environment—as traced by H I deficiency—on the rSFMS (top right), rMGMS (bottom left), and rKSR (bottom right) for the 15,401 pixels in our sample of 33 cluster galaxies. The same relations are shown for the resolution-matched HERACLES field sample (gray, 10,817 pixels, 10 galaxies). The distribution of H I deficiencies (top left) demonstrates the selection of the H I–normal (H I–def < 0.5 dex, blue) and H I–poor (H I–def ≥ 0.5 dex, red) subsamples. The relationships are shown using a Gaussian kernel density estimator with 10 isodensity contour levels linearly spaced between 5% and 100% of the distribution. The best fits are shown by the solid lines of corresponding color with the 1σ scatter illustrated by the shaded regions for the cluster subsamples and dashed lines for the field sample. Parameters and scatter of the best-fit relations are provided in Table 1 in the Appendix. The rSFMS and rMGMS in H I–normal galaxies follow the field relationships while the H I–poor galaxies have reduced SFR and molecular gas densities at fixed stellar mass.

The rMGMS fit for the H I–poor galaxies is offset below the H I–normal relation by 0.38 dex. Interestingly, the slopes of the H I–poor and H I–normal rMGMSs agree well (0.94 ± 0.013 and 0.94 ± 0.010 , respectively) with the H I–normal relation but is steeper than the field relation (0.79 ± 0.011). One reason for this is the lack of molecular gas at low stellar surface densities ($\Sigma_* \lesssim 10^{7.5} \text{ M}_\odot \text{ kpc}^{-2}$) in H I–poor galaxies, which implies that the impact of environment on the molecular gas disk is greatest in the low gas and stellar density regimes. In the context of the rSFMS analysis, the difference in molecular gas content for the H I–normal and H I–poor subsamples suggests that the link between global H I deficiency and subkiloparsec quenching is at least in part driven by a reduction in the molecular gas density.

The H I–poor rKSR (bottom right) is, on average, 0.24 dex below the fit to the H I–normal galaxies. This lower SFE in regions belonging to H I–deficient galaxies is also shown by

both Villanueva et al. (2022) and Jiménez-Donaire et al. (2023). The fact that the combined subsample offsets in rMGMS and rKSR match the observed offset in rSFMS is reflective of the fact that the locations of regions in the rSFMS plane are fundamentally a consequence of their position with respect to the rMGMS and rKSR (e.g., Lin et al. 2019; Ellison et al. 2020; Baker et al. 2022) and this, consequently, holds true for the best-fit relations as well.

The rKSR slopes for the H I–normal and H I–poor subsamples are very similar (0.84 ± 0.006 versus 0.82 ± 0.007), but flatter than is observed for the entire sample (0.97 ± 0.07 ; Jiménez-Donaire et al. 2023). This is likely a consequence of a nonlinear relationship between H I deficiency and molecular gas density, meaning the offset to lower SFR density is greatest for regions with high gas density in H I–poor galaxies.

Although it is clear that a linear fit is not the best descriptor of the data in each relationship, our goal here is simply to

provide a straightforward quantification of the offset between the H I-poor and H I-normal populations.

To quantify further the observed differences between regions belonging to H I-normal and H I-poor galaxies, we calculate the offset of each pixel from the median rSFMS, rMGMS, and rKSR of the full sample. These offset quantities are termed $\Delta\Sigma_{\text{SFR}}$, Δf_{mol} , and ΔSFE , respectively.

We define $\Delta\Sigma_{\text{SFR}}$ for each pixel following Ellison et al. (2020), using the relevant (VERTICO or HERACLES) sample itself to select a set of star-forming control pixels ($\text{sSFR} \geq 10^{-10.5} \text{ yr}^{-1}$) that are matched within a narrow range of stellar surface density ($\pm 0.1 \text{ dex}$) to the target pixel. We then calculate $\Delta\Sigma_{\text{SFR}} = \Sigma_{\text{SFR,pixel}} - \tilde{\Sigma}_{\text{SFR,control}}(\Sigma_*)$, where $\Sigma_{\text{SFR,pixel}}$ is the SFR surface density of the pixel and $\tilde{\Sigma}_{\text{SFR,control}}(\Sigma_*)$ is the median SFR surface density of the control sample. The sSFR threshold value was chosen to maximize the difference between the pixel sSFR distributions at fixed stellar density, i.e., regions with $\Sigma_* < 10^8 M_\odot \text{ kpc}^{-2}$ tend to have $\text{sSFR} > 10^{-10.5} \text{ yr}^{-1}$ and vice versa.

The result is that the median rSFMS is defined as $\Delta\Sigma_{\text{SFR}} = 0$, with positive and negative $\Delta\Sigma_{\text{SFR}}$ values for regions that are more star forming or more quenched with respect to this reference point. The normalization of this relation means that the median value of $\Delta\Sigma_{\text{SFR}}$ for all VERTICO pixels is -0.23 dex or, in other words, the median VERTICO pixel is $\sim 40\%$ less star forming than the median rSFMS.

We also quantify the molecular gas content and SFE by calculating the pixel offsets from the rMGMS and rKSR (Δf_{mol} and ΔSFE , respectively). Briefly, $\Delta f_{\text{mol}} = \Sigma_{\text{mol,pixel}} - \tilde{\Sigma}_{\text{mol,control}}(\Sigma_*)$, where $\Sigma_{\text{mol,pixel}}$ is the gas surface density of the pixel and $\tilde{\Sigma}_{\text{mol,control}}(\Sigma_*)$ is the median gas surface density of all pixels within $\pm 0.1 \text{ dex}$ in stellar surface density. Similarly, $\Delta\text{SFE} = \Sigma_{\text{SFR,pixel}} - \tilde{\Sigma}_{\text{SFR,control}}(\Sigma_{\text{mol}})$, where $\Sigma_{\text{SFR,pixel}}$ is the SFR surface density of the pixel and $\tilde{\Sigma}_{\text{SFR,control}}(\Sigma_{\text{mol}})$ is the median SFR surface density of all pixels within $\pm 0.1 \text{ dex}$ in molecular gas surface density. The only difference from the calculation of $\Delta\Sigma_{\text{SFR}}$ is that we do not impose an sSFR cut on the control samples for ΔSFE and Δf_{mol} . Thus, regions with positive (negative) Δf_{mol} values are gas normal (poor) with respect to the median rMGMS, and regions where ΔSFE is positive (negative) are forming stars more (less) efficiently than the median rKSR.

For the regions plotted in Figure 2, the median $\Delta\Sigma_{\text{SFR}}$ values for the H I-normal and H I-poor subsamples are 0 and -0.54 dex , respectively. This tells us, perhaps unsurprisingly, that our H I-normal sample tends to follow the median rSFMS for the entire population. Of course, this is mainly by construction given that we only include star-forming pixels when defining the $\Delta\Sigma_{\text{SFR}}$ control samples. Interestingly, pixels in the H I-poor subsample are a factor of ~ 3.5 less star forming than the rSFMS.

We take this analysis further by using the rMGMS to compare the Δf_{mol} values for our two subsamples. The median Δf_{mol} value for pixels in H I-normal galaxies is 0.01 dex . On the other hand, we find that pixels belonging to the H I-poor subsample have less molecular gas, with a median Δf_{mol} of -0.39 dex . The fact that the difference in median $\Delta\Sigma_{\text{SFR}}$ between the H I-normal and H I-poor galaxies is significantly larger than for Δf_{mol} tells us that suppression of molecular gas content is not the whole picture.

The regions belonging to the two subsamples also bracket the median rKSR, with pixels belonging to H I-normal and

Figure 3. Median ΔSFE as a function of stellar mass surface density, Σ_* for the H I-normal (blue) and H I-poor (red) VERTICO cluster subsamples and HERACLES field sample (gray). Error bars illustrate $\pm 1\sigma$ in each bin. The median ΔSFE (unbinned) for each subsample is shown by the dashed line of the corresponding color. Pixels belonging to H I-poor galaxies have lower SFEs at fixed stellar mass surface density.

H I-poor galaxies having median ΔSFE values of 0 and -0.22 dex , respectively. Again, this clearly shows that by selecting pixels based upon their host galaxy's H I deficiency, we are selecting subsamples of pixels with significantly different SFEs. Although trivial, it is important to note that the combined difference in the mean values of Δf_{mol} and ΔSFE values (0.6 dex) between the H I-normal and H I-poor subsamples closely matches the difference in $\Delta\Sigma_{\text{SFR}}$ of 0.54 dex . In fact, the residual 0.06 dex is well within the typical pixel uncertainties of these quantities of 0.1 dex .

It is clear from Figure 2 that the H I-poor galaxies do not cover the same range in stellar mass surface density as either the HERACLES or H I-normal galaxies in VERTICO. While this difference is controlled for when calculating Δf_{mol} and $\Delta\Sigma_{\text{SFR}}$, it is not when computing ΔSFE . Thus, it is important to check that the observed differences in the rKSR for the H I-normal and H I-poor galaxies are not caused by stellar surface density selection effects. Figure 3 shows the median ΔSFE values of pixels belonging to H I-normal, H I-poor, and HERACLES galaxies at fixed stellar mass surface density. In each bin, the median ΔSFE for regions in the H I-poor galaxies is lower than for regions in the H I-normal and field galaxies. Interestingly, the difference between H I normal and H I poor is largest at lower Σ_* , where one would expect environmental mechanisms to be most effective. Figure 3 demonstrates that the offset of the H I-poor rKSR to lower SFEs shown in Figure 2 is not caused by different stellar mass density distributions between the two samples.

In an effort to understand the physics driving these trends, we now look to confirm the connection between environmental mechanisms and H I deficiency in our sample and connect the influence of these mechanisms on the gas-star formation cycle back to the rSFMS, rMGMS, and rKSR.

3.2. The Connection Between H I Deficiency and Evolutionary Stage within the Cluster

We interpret the differences seen in Figure 2 as evidence that environmental processes are responsible for the systematic quenching of Virgo galaxies on subkiloparsec scales. However, this assumes that H I deficiency is an effective quantitative measure of environmental influence on VERTICO galaxies.

Figure 4. The distribution of galaxy H I deficiency for distinct RPS stages compiled from Yoon et al. (2017). The box shows the quartiles of the distribution while the whiskers extend to the full range in values. The number of galaxies in each stage is written next to the box. H I deficiency increases as RPS proceeds.

The large body of work that underpins this assumption is detailed in the [Introduction](#) and we can also demonstrate this explicitly for our sample.

Yoon et al. (2017) provide classifications of environmental influence for the VERTICO targets based on a comparison of H I morphology with their orbital history. These authors identify distinct RPS stages (early, active, and post), as well as two other classes for unperturbed and anemic (i.e., low surface density) H I disks. Yoon et al. (2017) suggest that the anemic galaxies are likely undergoing starvation and/or thermal evaporation. While this may be true, our view is that making this distinction implies that ram pressure is not at play, which is unlikely since these galaxies have been in the cluster for more than one pericenter passage and have comparable H I extents to the other classes at fixed H I deficiency. Additionally, unlike the other classes, the anemic disks are also only present at high stellar mass (Yoon et al. 2017). Thus, we suggest that anemic disks are a case where environmental processes such as RPS have removed the H I in the outskirts, but not all the H I in the inner regions (perhaps due the large stellar mass of the galaxy), and there is no significant accretion of new gas onto the disk.

Figure 4 uses the data of Yoon et al. (2017) to illustrate the dependence of H I deficiency upon the gas stripping histories of galaxies previously identified by those authors. The H I content of galaxies is systematically depleted as galaxies transition from unperturbed disks through the early, active-, and post-RPS stages. The anemic disks are also very H I deficient, although generally not to the extent of the highly truncated post-RPS class.

3.3. Radial Variations in Environmental Influence

In Figure 5, the panels from left to right show the distribution of $\Delta\Sigma_{\text{SFR}}$, Δf_{mol} , and ΔSFE pixel values as a function of host

galaxy H I-identified evolutionary stage. We include the HERACLES galaxies as our field sample in addition to the environmental classes identified by Yoon et al. (2017) and shown in Figure 4. The distributions are separated into pixels from the inner and outer disk based up on whether they fall inside or outside of the galaxy’s 90% molecular gas mass–radius relation published by Brown et al. (2021; $r_{90,\text{mol}}$ in their Table 3). The median value of each distribution is shown by the dashed lines, while the dotted lines show the 25th and 75th percentiles, respectively.

Local SFR decreases as a function of RPS stage. This quenching is most apparent in the outer disk where the median values of $\Delta\Sigma_{\text{SFR}}$ in the early, active-, and post-RPS phases are 0.18, -0.18 , and -0.65 dex, respectively. In comparison, in the inner disk during these same phases, the median values of $\Delta\Sigma_{\text{SFR}}$ are 0.08, -0.07 dex, and -0.12 dex, respectively. The observed star formation quenching as galaxies are stripped is primarily driven by decreases in the molecular gas content, with a secondary dependence on SFE. As with star formation activity, the effects of RPS on molecular gas are most pronounced in the outer disks where galaxies in the early, active-, and post-RPS stages have median values of Δf_{mol} of 0.31, -0.11 , and -0.47 dex, respectively (inner disk median $\Delta f_{\text{mol}} = 0.07$, -0.06 , and -0.24 dex, respectively). There is also a significant decrease in the SFE of the outer disks during RPS, although considerably less than for molecular gas. The median values of ΔSFE in the outer disks of the early, active-, and post-RPS phases are -0.01 , -0.12 , and -0.33 dex, respectively (inner disk median $\Delta\text{SFE} = 0.01$, -0.07 , and -0.17 dex, respectively). In summary, by the time the H I disk of a galaxy is fully stripped (“post RPS”) its molecular gas content has reduced by a factor of 1.7 (0.24 dex) and 3 (0.47 dex) in the inner and outer regions, respectively. This drives quenching in both radial bins that is compounded by the simultaneous reduction in the SFE (factors of 1.5 and 2.1, respectively).

The star formation activity of anemic disks is quenched to a similar extent to the post-RPS phase. However, unlike galaxies in the RPS phases, anemic galaxies are quenched across the disk with a median $\Delta\Sigma_{\text{SFR}}$ of -0.6 and -0.56 dex in the inner and outer regions, respectively. This is caused by the suppression of molecular gas content and SFE throughout the galaxy (median $\Delta f_{\text{mol}} = -0.50$ and -0.49 dex and median $\Delta\text{SFE} = -0.22$ and -0.22 dex, for inner and outer disks, respectively).

Figure 5 shows that for galaxies following the classic RPS sequence, environment acts to decrease gas content and SFE, especially in the outskirts, resulting in the outside-in quenching of star formation. On the other hand, there is a comparable decrease in gas content and SFE for the anemic disks of high-mass galaxies, but the effect is found in both the inner and outer disk.

Even in galaxies with morphologically unperturbed H I disks, we see suppression of local star formation in the outer disks (median $\Delta\Sigma_{\text{SFR}} = -0.15$ dex). This may be the result of “preprocessing” of galaxies in the group environment or outermost regions of the cluster (Fujita 2004). This appears to be driven solely by reduced gas content (median $\Delta f_{\text{mol}} = -0.34$ dex), with SFEs typical of the field (median $\Delta\text{SFE} = -0.02$ dex).

We also see enhanced star formation activity driven by increased gas densities with respect to the field in the earliest

Figure 5. The distribution of $\Delta\Sigma_{\text{SFR}}$, Δf_{mol} , and ΔSFE pixel values for galaxies in different evolutionary stages. Field galaxies are drawn from the HERACLES sample, while H I–identified RPS stages and anemic disks are taken from Yoon et al. (2017). Pixel distributions are divided into the inner and outer disk ($r < r_{90,\text{mol}}$ and $r \geq r_{90,\text{mol}}$, respectively). We annotate the number and percentages of pixels in the inner and outer disks for each stage in the corresponding color. The gray horizontal bar simply illustrates the distinction between our field and cluster samples. We see the systematic decrease in $\Delta\Sigma_{\text{SFR}}$, Δf_{mol} , and ΔSFE during the stripping sequence and also in anemic disks with respect to the field. The reduction in gas content and SFE, and consequently star formation activity, happens preferentially in the outer disks for galaxies undergoing RPS.

RPS stage, with the effect again most prominent in the outer disk. The median Δf_{mol} in the outer disks of these galaxies is 0.31 dex, while the inner disk exhibits a typical field value of 0.07 dex. Although the number of galaxies in the stage is small (four), this result agrees with a picture from other surveys where ram pressure initially increases gas content before quenching (e.g., Moretti et al. 2020a; Cramer et al. 2020; Troncoso-Iribarren et al. 2020; Roberts et al. 2022). At face value we appear to contradict the result of Watts et al. (2023) who find no evidence for environment-driven increases in molecular gas densities in VERTICO galaxies. However, Watts et al. (2023) are comparing much coarser subsets of the VERTICO galaxies divided into three bins of H I deficiency. Figure 5 demonstrates that the increase in gas densities due to ram pressure is only apparent in the earliest stage of stripping identified by the Yoon et al. (2017) morphology and phase-space analysis. Furthermore, the effect in the inner regions is relatively subtle, only becoming prominent in the outskirts of the galaxy gas disk which are not explicitly examined by Watts et al. (2023). Our result is also in agreement with Roberts et al. (2023) who observe increased gas densities on the leading half (with respect to their trailing half) of VERTICO galaxies undergoing RPS. Finally, we also see that in the field galaxies, it is the inner disk that has reduced molecular gas content and star formation activity, which may be indicative of secular processes regulating the star formation cycle in these galaxies.

This analysis suggests that the environmental mechanisms causing global H I deficiency are also systemically and significantly reducing molecular gas content and SFE, and consequently star formation activity, on subkiloparsec scales in cluster galaxies. The influence of RPS increases as the stripping

processes proceed, occurring preferentially in the disk outskirts. The star formation cycle of galaxies with anemic H I disks, likely caused by starvation of the gas supply, is impacted to a similar extent as the post-RPS galaxies. However, the effect of starvation is commensurate in both the inner and outer disk. In the next section, we discuss the physical causes of H I deficiency in Virgo Cluster galaxies, their connection to molecular gas content, and the local and global star formation cycles.

4. Discussion

Our results show that regions belonging to more H I–deficient galaxies typically have lower molecular gas content and SFEs at fixed stellar surface density, and therefore less star formation activity than their counterparts in H I–normal galaxies (Figures 2 and 3).

Figure 4 shows that the H I–poor subsample ($\text{HI-def} \geq 0.5$) includes galaxies with H I disks that have already been severely stripped (“post RPS”), a subset of those that are still undergoing stripping (“active RPS”), and galaxies that are primarily undergoing starvation rather than stripping (“anemic disk”). On the other hand, the H I–normal subsample ($\text{HI-def} < 0.5$) combines galaxies with relatively unperturbed H I disks and those in the earliest phase RPS (“early RPS”) with the remaining, more H I–rich, galaxies that are experiencing stripping (“active RPS”). Thus, the observed differences between the H I–normal and H I–poor subsamples in the rMGMS and rKSR (Figure 2) are evidence that environmental processes are driving a systematic reduction in molecular gas density and SFE on subkiloparsec scales in our galaxies.

Figure 5 takes the analysis further by demonstrating that for galaxies undergoing RPS, the magnitude of this decrease is

correlated with infall stage and the location within the disk. The lower median $\Delta\Sigma_{\text{SFR}}$, Δf_{mol} , and ΔSFE in the outer disk of active and post-RPS galaxies can be interpreted as differences in the rSFMS, rMGMS, and rKSR for regions inside and outside of the galaxy truncation radius.

In comparison, the anemic disks are similarly effective at reducing gas content and SFE, however, this influence is seen in both the inner regions and outskirts of disk. This suggests that the gas reservoir that remains after stripping in these galaxies is primarily being consumed by ongoing star formation rather than being directly affected by external processes which one would expect to act more strongly on the outer disk.

Gas content and SFE are both reduced in galaxies undergoing RPS and starvation, and the quantitative influence of the environmental mechanisms is always largest on the gas content. The fact that we see a significant reduction in the gas content and star formation activity in the active- and post-RPS galaxies suggests that a significant impact on the star formation cycle only occurs in the more advanced stripping stages. In other words, there is a threshold point at which gas stripping becomes an effective quenching mechanism. Prior to this point, in the early RPS stage, we see enhanced star formation activity that is driven only by increased gas density (at fixed stellar density) with no measurable change in the SFE. We also see tentative evidence for a reduction in the molecular gas densities in the “unperturbed” cluster galaxies which is possibly due to preprocessing prior to cluster infall.

It is reasonable to question whether the observed trends in Figure 2 are being wrongly attributed to environment and are instead governed by secular processes. Indeed, a number of works have shown that gas content and SFE is reduced in field galaxies transitioning from star forming to quiescence (i.e., green valley) using both global and resolved measurements (Brownson et al. 2020; Colombo et al. 2020; Ellison et al. 2021; Lin et al. 2022; Saintonge & Catinella 2022). However, the fact that the reduction in gas content and SFE is correlated with H I-identified environmental influence and location within the galaxy disk (Figure 5) suggests outside-in quenching mechanisms rather than secular processes that are associated with the presence of stellar structure in the inner disk (e.g., bars and bulges). Furthermore, there are only four active galactic nuclei (AGN) in our sample, two of which are in the H I-poor sample, so AGN feedback is not a major driver of our results (NGC 4388, NGC 4536, NGC 4579, and NGC 4772; Esparza-Arredondo et al. 2018; Gavazzi et al. 2018; Lee et al. 2022).

4.1. The VERTICO View of Quenching in Virgo Galaxies

To refocus this discussion on the bigger picture of how environment regulates the star formation cycle in VERTICO galaxies, we now place our results in the context of the four previous VERTICO science papers described in Section 1: Zabel et al. (2022, hereafter Z22), Villanueva et al. (2022, hereafter V22), Jiménez-Donaire et al. (2023, hereafter JD23), and Watts et al. (2023, hereafter W23).

Z22, V22, and W23 all find evidence for the systematic decrease in molecular gas content in H I-deficient galaxies that we see in this work. W23 shows that this environment-driven suppression occurs across the galaxy disk, both inside and outside of the truncation radius. Along with Z22, they also demonstrate that low-density molecular gas is preferentially affected. While gas content is suppressed across the disk, Z22

and V22 use radial analyses to show that molecular gas disks in VERTICO are more centrally concentrated than in field galaxies, with galaxies impacted by their environment showing steeper and/or truncated gas density profiles. These results clearly align with the offset of the H I-poor rMGMS to lower gas densities (Figure 2) and the reduction of gas content as a function of environment and location within the disk (Figure 5). Taken together, this demonstrates that environmental processes have a predominantly destructive effect on molecular gas reservoirs throughout the disk, with the low-density gas in the outskirts of galaxies affected first and foremost.

As shown in this work, environmental impact on the amount of molecular gas available for star formation is not the only factor. V22 show that the SFE of molecular gas within the stellar radius decreases with increasing environmental perturbation. JD23 complete a more detailed investigation of the rKSR than in this work and are the first to report the lower SFEs in H I-deficient galaxies with respect to H I-normal cluster galaxies, with the latter following the relationship found in field galaxies. As well as the longer depletion times in galaxies undergoing environmental transformation, JD23 also find significant galaxy-to-galaxy and region-to-region variations in the SFE, suggesting there is no single rKSR that can be used to describe all cluster galaxies accurately. We do note that this galaxy-to-galaxy diversity in the SFE is also found in field galaxies (e.g., Ellison et al. 2021; Casasola et al. 2022; Saintonge & Catinella 2022). So, while the correlation with stripping stage and lower SFE in the outer disks in Figure 5 suggests environmental processes are at play, we have not yet precisely determined the extent to which the cluster environment is responsible for decreasing the efficiency with which galaxies convert their molecular gas into stars.

We do, however, demonstrate that environment generally acts to reduce both the molecular gas content and SFE throughout the disks of Virgo galaxies, albeit preferentially in the outer regions for galaxies undergoing stripping. In an effort to identify the particular environmental process(es) responsible for these effects, we use existing H I morphological classifications to show that the observed reduction in gas content, SFE, and activity in H I-poor VERTICO galaxies increases with RPS stage. We also investigate the effect that the lack of gas accretion after parts of the disk have been stripped (i.e., starvation) has on the star formation cycle in the remaining disk. We demonstrate that the gas content and SFE of starved galaxies are negatively influenced to the same degree as stripped galaxies, although the reduction is uniform throughout the remaining disk, which suggests ongoing star formation is primarily responsible.

In support of a picture where ram pressure strongly regulates the star formation cycle of most H I-poor VERTICO galaxies, V22 show that the ratio of molecular to atomic gas (R_{mol}) increases within the stellar radius with the level of H I truncation and/or asymmetry. In the same vein, W23 observe a decrease in molecular gas content and increases in R_{mol} that cannot be driven by changes in the ISM physical conditions alone and invoke stripping of the molecular gas to explain their results. The RPS scenario is also entirely consistent with the preferential suppression of low-density gas in the outskirts seen in our work, as well as the steep and truncated gas density profiles in H I-deficient galaxies (Z22; W23; V22).

In agreement with previous work focusing on local versus global quenching (e.g., Bluck et al. 2020, 2022), our results and

those of JD23 show that in Virgo the two go hand in hand. Indeed, JD23 report that H I-deficient VERTICO galaxies are offset below the global SFMS for field galaxies by 0.6 dex. In our work, we show subkiloparsec regions belonging to H I-poor galaxies are, on average, a factor of ~ 3.5 (~ 0.54 dex) less star forming than their counterparts in H I-normal systems. Given that H I deficiency broadly traces stripping stage in our sample (Figure 4), this shows that RPS quenches star formation on both local and global scales in VERTICO galaxies. The analysis of Figure 5 suggest that stripping acts from the outside-in to suppress gas content and SFE throughout the disk.

Lastly, we note that we find evidence for the elevation of star formation activity driven by increased molecular gas densities at fixed stellar mass in the earliest stripping stage, especially in the outskirts. In combination with Roberts et al. (2023), who find gas compression on the leading half of RPS VERTICO galaxies, these results suggest that although ram pressure is ultimately a global quenching process, its initial effect is to induce local star formation activity driven by systematic gas compression prior to removal. Neither this work nor Roberts et al. (2023) find evidence for increased SFE due to RPS and, while JD23 find azimuthal variations in the SFE in two VERTICO galaxies, only one of these (NGC 4654) has a clear signature of an enhanced SFE on the leading edge. One such instance in the entire 49 CO-detected galaxies in VERTICO supports our conclusion that this scenario is the exception rather than the rule, at least at the sensitivity and resolution of our observations.

5. Summary and Conclusions

This paper presents the first galaxy cluster rSFMS using 15,401 subkiloparsec regions drawn from 33 Virgo members in the VERTICO survey. We also revisit the rMGMS and rKSR shown by previous VERTICO work (W23; JD23). The influence of environment on the subkiloparsec star formation cycle of Virgo galaxies is characterized by dividing the selected pixels into subsamples belonging to H I-normal ($\text{H I-def} < 0.5$) and H I-poor ($\text{H I-def} \geq 0.5$) galaxies. We then compare the differences in the gas content, SFE, and star formation activity of regions with respect to the median relation as a function of their location within the disk and host galaxy evolutionary stage. This analysis has produced a number of results which we summarize here:

1. H I-poor galaxies have lower SFR surface densities with respect to H I-normal cluster and field galaxies at fixed stellar mass surface density. The median $\Delta\Sigma_{\text{SFR}}$ of H I-poor galaxies is 0.54 dex lower than for H I-normal systems (Figure 2). We conclude that the decrease in star formation activity in H I-poor galaxies is due to the combined effects of reduced molecular gas content and SFE.
2. The median molecular gas content (as quantified by Δf_{mol}) of regions belonging to H I-poor galaxies is a factor of three (0.54 dex) lower than regions in H I-normal galaxies (Figure 2) at fixed stellar mass surface density. The difference increases with decreasing molecular gas density, suggesting that the low-density gas is preferentially affected. This result supports the previous work by Z22 and V22.
3. Regions in the H I-poor subsample have -0.22 dex lower SFE at fixed Σ_* than H I-normal galaxies, suggesting that environmental mechanisms are responsible for the

observed decrease in the SFE in Virgo (Figures 2 and 3), supporting the previous work by JD23 (Figure 2).

4. We observe systematically enhanced SFRs and molecular gas surface densities at fixed stellar density (0.18 dex and 0.31 dex, respectively) in the earliest stage of RPS at fixed stellar surface density, while the SFE remains unchanged (Figure 5). This effect is most pronounced in the outer disks of galaxies.
5. Galaxies that have undergone starvation of their gas supply (likely in addition to RPS) have similarly reduced star formation activity, molecular gas content, and SFE to the outskirts of truncated RPS galaxies (Figure 5). However, the influence of starvation on the star formation cycle occurs throughout the disk, suggesting that it is an effective quenching mechanism in the remaining gas disk not affected by ram pressure, which primarily affects the outer regions.

This paper presents a coherent picture of how environmental mechanisms, in particular RPS and starvation, regulate the star formation cycle in VERTICO galaxies. Future work will focus on outstanding questions such as: what are the physical drivers of the variation in SFE? How does environment regulate molecular gas kinematics? By answering these questions, VERTICO will give us a more complete understanding of the gas–star formation cycle in cluster galaxies.

Notes. The units are given in Figure 2. Pivot is in the same units as x . The rms scatter, σ , of the data about the fitted relation is calculated as the standard deviation of $y_{\text{fit}} - y_{\text{pix}}$. For the rKSR, we fit for Σ_{mol} as the uncertainties are larger than for Σ_{SFR} and rearrange the fit result for $y = c + mx$ where $c = -a/b + \text{pivot}$ and $m = 1/b$.

Parts of this research were supported by the Australian Research Council Centre of Excellence for All Sky Astrophysics in 3 Dimensions (ASTRO 3D), through project number CE170100013.

This paper makes use of the following ALMA data:

1. ADS/JAO.ALMA #2019.1.00763.L
2. ADS/JAO.ALMA #2017.1.00886.L
3. ADS/JAO.ALMA #2016.1.00912.S
4. ADS/JAO.ALMA #2015.1.00956.S

ALMA is a partnership of ESO (representing its member states), NSF (USA) and NINS (Japan), together with NRC (Canada), MOST and ASIAA (Taiwan), and KASI (Republic of Korea), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AUI/NRAO, and NAOJ. The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.

This research made use of data provided by NASA/IPAC Infrared Science Archive, which is funded by the National Aeronautics and Space Administration and operated by the California Institute of Technology.

The authors acknowledge the use of the Canadian Advanced Network for Astronomy Research (CANFAR) Science Platform. Our work used the facilities of the Canadian Astronomy Data Center, operated by the National Research Council of Canada with the support of the Canadian Space Agency, and CANFAR, a consortium that serves the data-intensive storage, access, and processing needs of university groups and centers engaged in astronomy research (Gaudet et al. 2010).

Facilities: ALMA, GALEX, Sloan, and WISE.

Software: The Ancillary Data Button¹⁹ (Clark et al. 2018), ASTROPY²⁰ (Astropy Collaboration et al. 2013; Price-Whelan et al. 2018; Bradley et al. 2020), MATPLOTLIB²¹ (Hunter 2007; Virtanen et al. 2020), PANDAS²² (McKinney 2010), RSMF²³, SciPy²⁴ (Virtanen et al. 2020), and SEABORN²⁵ (Waskom 2021).

Data Availability

The molecular gas, SFR, and stellar mass surface density maps for all VERTICO galaxies are publicly available for download from the Canadian Advanced Network for Astrophysical Research VOSpace cloud storage (Brown & The VERTICO Collaboration 2023). Note that the online maps are not corrected for galaxy inclination. The data set and the Jupyter notebook used to perform this analysis are publicly available on Zenodo at doi:10.5281/zenodo.8253768 and on GitHub.²⁶

Appendix Best-fit Parameters for Figure 2

Table 1 provides the best-fit parameters and scatter for the H I-poor and H I-normal subsamples in the rSFMS, rMGMS, and rKSR shown in Figure 2. The fits and scatter are derived using the LTSFIT package; for more details see Section 3.2 of Cappellari et al. (2013). In this work, we keep the limit on the fraction of possible outliers at its default value of 50% but this choice does not strongly influence our results.
